Two-Transistor Circuit with Polarity Reversal of Mean Output

The parallel transistor circuit of Fig. 4(A) has equal triggering periods in each half-cycle of operation, since a given signal sense causes either an advance or retard of switching in both half-cycles. Polarity-reversing characteristics are obtained, however, if the circuit is revised so that the switching angle advances in one half-cycle and retards in the other for a given signal sense. By the reversal of one signal winding as in Fig. 5(A), this effect is achieved. Fig. 5(B) illustrates bias and signal conditions that result in triggering angles θ and ϕ and these give an output voltage wave form as in Fig. 5(C).

For a 90-degree lead of the bias voltage the switching angles are given by

$$\cot\theta = \frac{V_{\rm sig}}{V_{\rm bias}} \qquad (7)$$

where $0 < \theta < 180°$

$$\text{and } \cot\phi = -\frac{V_{\rm sig}}{V_{\rm bias}} \qquad (8)$$

where $180° < \phi < 360°$

Alternatively to equation 8, it can be seen from symmetry that

$$\phi = 2\pi - \theta \qquad (9)$$

By simple integration, the mean output (i.e., direct component of the load voltage) is

$$V_{\rm load} = \frac{V_p}{2\pi}(\cos\theta + \cos\phi) \qquad (10)$$

$$= \frac{V_p}{\pi}\cos\theta \qquad (11)$$

The maximum output is therefore ±

C—Bias and signal voltage wave forms, 90-degree lead bias
D—Load voltage output of circuit A for a-c signal
E—Load voltage output of circuit A for d-c signal

V_p/π and for zero signal input the output is zero, since $\theta = 90$ degrees. The theoretical output characteristic (positive quadrant only, since the curve is symmetrical) calculated from equations 7 and 11 is given in Fig. 5(D). The sensitivity in the region of zero signal is given by

$$\frac{d(V_{\text{load}})}{d(V_{\text{sig}}/V_{\text{bias}})} = \frac{V_p}{\pi} \tag{12}$$

With the experimental circuit arranged to give reversing polarity output, curve 1, Fig. 6, was the characteristic obtained. The crosses shown in the positive quadrant are points calculated from the theoretical characteristic of Fig. 5(D) and these are in good agreement with the experimental curve. The gain of this arrangement was not high; for example, for a signal of 5 volts the input was about 0.1 volt-ampere and the output about 1.0 volt-ampere (mean). However it should be recognized that the circuit is performing the dual functions of phase-sensitive rectification and amplification.

With zero bias voltage, switched operation does not occur, and the experimental curve obtained was curve 2, Fig. 6. The output wave form was roughly a half-cycle sinusoid of varying amplitude existing between 0 and π, or π and 2π, depending on the signal magnitude and sense. The transistors sustain voltage and conduct current simultaneously, and the heat dissipation therefore is a limiting factor in this nonswitched mode of operation.

Some Other Circuit Arrangements

The basic switching amplifier concept may be applied in numerous circuit forms containing two or even four transistors. Many of these are analogous to magnetic-amplifier circuits since the saturating core elements in the latter may be regarded as switches of high or low impedance, depending on the flux and magnetomotive-force conditions. The transistor circuit, Fig. 4(A), for example, is nearly equivalent to the magnetic-amplifier doubler circuit in output wave form.

There are, of course, differing features in the two arrangements. For instance, in the transistor circuit the periods of switch-off and switch-on can be interchanged within the half-cycle (i.e., load voltage can be taken in the period 0-θ instead of θ to π) by reversing the signal and bias polarities. This possibility does not exist in the magnetic-amplifier doubler circuit for reasons in connection with the required flux changes.

The signal input to a magnetic amplifier is usually d-c but this is not always so.[5] Magnetic-amplifier stages with a-c control tend to be of low or moderate gain but to respond within half a cycle of the supply frequency to any signal change, as do the switching transistor amplifiers described.

The transistor circuit in Fig. 7(A) is analogous to the commonly used magnetic-amplifier bridge circuit and it provides an output that is a rectified version, Fig. 7(B), of that given by the parallel circuit Fig. 4(A). The circuit shown in Fig. 7(C) resembles the center-tap magnetic-amplifier connection and may have one of several arrangements of signal and bias control. With the bias and a-c signal inputs common for both transistors as shown, the output wave form, Fig. 7(E), is obtained. Since θ and ϕ advance or retard together with change of signal amplitude, the effect is equivalent to a phase shift of the a-c component of output with the d-c component remaining constant. On the other hand, if the signal is d-c instead of a-c, the second switching angle becomes ϕ' instead of ϕ as shown in Fig. 7(D), and the d-c component of output then varies, as θ and ϕ' move apart or approach each other, with signal change. If separate bias secondary windings are used, the bias for one transistor may be reversed and then the output wave forms given by a-c and d-c signals will interchange.

In the design of switching amplifiers proper consideration must be given to the disposition of the signal and bias voltages to ensure that complete switch-on or switch-off occurs. For example, if the collector in a p-n-p transistor is positive with respect to the emitter by the extent of the supply voltage, and if the control voltage is placed between base (positive) and emitter, switch-on occurs when the supply voltage exceeds the control. But conduction occurs with the transistor sustaining a voltage between collector and emitter about equal to the control voltage, because only under this condition is the base negative with respect to an electrode (i.e., in this case, to the collector). This corresponds to an example of imperfect switch-on in a circuit arrangement that is best avoided. Another factor to be considered in circuit design is that in fused-junction transistors the construction is usually such that the inverted mode of operation (i.e., with the collector behaving as emitter) requires appreciably more base current drive for a given output current flow.[2]

With two similar transistors, these principles tend to preclude the use of signal and bias inputs that are common for both units, and therefore input transformers are usually required. However, if the complementary symmetry of p-n-p and n-p-n units is utilized, the circuit arrangements lend themselves more readily to common control inputs, as shown in Fig. 8.

For the parallel Fig. 8(A), with a-c signal and bias wave forms as in Fig. 8(C), the n-p-n transistor conducts between θ and π, because its base is then positive and the p-n-p transistor conducts between $\pi + \theta$ and 2π with its base negative. The output voltage wave form is therefore as shown in Fig. 8(D), and is the same as that in Fig. 4 for the transformer input circuit. On the other hand, if the signal is d-c the switching angles from Fig. 8(C) are θ' and ϕ' and the output wave form is as shown in Fig. 8(E). This resembles the wave form of Fig. 5(C), produced in the simple p-n-p circuit by an a-c signal. The circuit in Fig. 8(B) is a bridge version of Fig. 8(A) and provides a rectified load output.

Conclusions

A switched mode of operation for transistor power amplifiers results in very low power loss in the transistor and therefore the temperature rise is small and the transistor retains appreciable power-handling capabilities up to high ambient temperatures. The characteristics obtained are of lower gain than for linear operation but are correspondingly less sensitive to changes in the actual transistor parameters. The switched output wave forms tend to resemble those of magnetic amplifiers, and certain circuits are analogous.

Within the scope of this paper it is not possible to discuss matters such as the influence of load on circuit behavior, circuits requiring more than two transistors, and circuit techniques for transistor stages preceding such amplifiers. However, the general concept appears promising and should repay continued circuit investigation.

Heat as a Means of Air Purification

C. E. CLIFTON
NONMEMBER AIEE

Synopsis: These studies support the view that high-temperature heaters, such as the ceramic-type incandescent electric heater, exert a considerable bactericidal and sporicidal effect. When in operation in the home, the rates of reduction of air-borne micro-organisms generally are of the order of 50 per cent per hour for the more resistant spores. Where these electric heaters are the principal source of heat for a given home or room, it is reasonable to expect that the micro-organism content will reach a very low level after several hours of operation. It is clear that a considerable portion of the air circulating around the heater may not soon pass close enough for the organisms contained therein to be destroyed. It takes several hours of operation to achieve a stable minimum condition. The germicidal action appears to be much more rapid than that of ultraviolet light as ordinarily placed in a room but not so fast as with the use of a chemical material such as propylene glycol vapor.

MANY developments in recent years have given cause for concern about air contamination. The advent of irritating smog in urban areas, the threat of biological warfare, and the increasing awareness that air contamination is a health hazard have stimulated thought on this subject. Mechanical filters of various sorts have been used rather successfully but too few people are aware that the proper application of heat can be effective. The use of heat to purify the air may seem new to some, but it has been applied for many years in the exhaust-air systems of bacteriological laboratories.

Air purification in the home should not involve the control of a large volume or weight of objectionable material. Ideally, domestic air-cleaning equipment must be simple; it must have a low first cost, low operating cost, no significant maintenance cost, and require no regular inspection. It is logical to consider air-purification equipment as part of the heating or air-conditioning system rather than as a separate piece of equipment, though it may be separate when more convenient.

Objectionable Contaminants

Of the many contaminants present in the air in homes, by far the most common and potentially the most harmful are living organisms such as mold spores, bacteria, and viruses. Toxic chemicals seldom occur and, because of the small quantities encountered, are primarily dangerous only because they may weaken resistance to infection.

Among these toxic chemicals, the most common in the home is ozone. There has been much confusion regarding the hazard of ozone. Though it may have limited usefulness in the control of objectionable odors, it is generally to be avoided,[1] and is recognized by medical authorities to be a health hazard when more than 0.10 ppm (part per million) is present.[2] In Los Angeles 0.80 ppm (under severe smog conditions) has been authoritatively reported by the Stanford Research Institute.[3] Smog alerts are proclaimed whenever the ozone concentration exceeds 0.50 ppm.

Other common harmful contaminants include pollens and ordinary house dust. It is well known medically that some persons are sensitive to pollens and to house dust (particles of wool-down, cotton, etc.). Pollens are relatively large in size, many being visible without the aid of magnification; they are easily filtered from the air. However, both pollens and house dust, or lint, can be destroyed by heat if the heat is of sufficient intensity and the time of exposure relatively long. These particles generally have adequate mass to impinge on the hot surfaces of the heater and incineration has been visually observed.

Existing Methods of Air Purification

There are three available means of controlling air-borne contaminants in use today. These are well developed commercially and are reviewed here briefly.

OIL AND PROPYLENE GLYCOL

It is well known that contamination of the air in living areas is markedly affected by the dispersion of organisms during sweeping, bed making, and similar activities. The spreading of certain oils on floors quickly results in a reduction of the atmospheric bacterial count, reductions of 80 per cent having been reported.[4] Though this is an effective means of control of air-borne contaminants, it is not a welcome one to the home owner. This expedient appears to be both inconvenient, and, to a degree, impractical in the home.

Although propylene glycol has been used effectively and its lethal effect on bacteria and viruses is well known, it, too, is very inconvenient for use in the home. No one desires to maintain a vaporizer continuously generating glycol vapor, because of the humidity problem and the condensation that takes place. This means of air purification, therefore, is not practical except in unusual circumstances.

ULTRAVIOLET RADIATION

An accurate evaluation of ultraviolet radiation to control air-borne organisms as compared with heaters of the type described here is difficult because of the many variables that exist. A heater designed for the purpose has the distinct advantage over ultraviolet lamps placed along the upper part of the walls in that the heater circulates a substantial volume of air, whereas the lamps do not. Such a heater, placed close to the floor, has a better chance to intercept contaminants or secondary aerosols stirred up by walking. The lamps, on the other hand, located high for safety, will have little effect on secondary aerosols. They have the further disadvantage that, if powerful enough to do an effective job in a room in the home, they will also generate ozone. Ozone cannot be tolerated where the background is already too high because of urban air pollution. There is also the problem of visible light that might interfere with sleeping and the hazard to the eyes of the wall-type lamps when they are not mounted high enough.[5]

Ultraviolet lamps undoubtedly have their proper application in air purification—as in hospitals and public places where a good engineering job of placement and ventilation can be obtained. They can be used at all times of the year, whereas an electric heater is limited to cold-weather use. Limitation of the electric heater to wintertime is not important so far as home use is concerned when it is considered that most respiratory infections occur during the cold months and that ventilation, an excellent means of purification except in smog areas, is generally adequate in summer for the control of bacteria and viruses in the air.[6]

Paper 56-236, recommended by the AIEE Electrical Techniques in Medicine and Biology Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted November 17, 1955; made available for printing February 28, 1956.

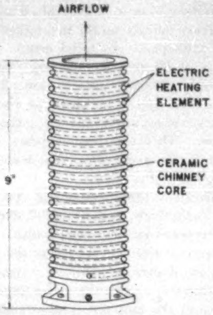

Fig. 1. Electric heating element showing hollow chimney-type ceramic core with resistance wire coil

Recently, attempts have been made to use ultraviolet radiation in ventilation systems in large buildings.[7] It was noted in this study that the percentage of destruction of bacteria (coli) was greater with the heater as compared with reported values with lamps, except when the microwatts per second per square centimeter of the lamps approached high levels.

ELECTROSTATIC AIR CLEANERS

The use of electrostatic devices for air cleaning is also well known. There are two main objections to this means of purifying air: 1. the first cost of the equipment is high, placing it out of reach of most home owners; and 2. there is always the problem of re-entrainment of dust and micro-organisms after collection. Where a regular program of cleaning of the places can be instituted, or where expensive automatic means for periodic plate cleaning is acceptable, this is an entirely satisfactory solution. However, it must be kept in mind that this is essentially a collection device and does not destroy the objectionable material. Proper use of heat positively assures that the air-borne contaminants are destroyed. This was an important consideration when an incandescent brick chimney was selected for the Naval Bacteriological Laboratories at Oakland, Calif., as the only known safe method for disposing of air-borne pathogenic organisms from ventilation exhaust systems.

Associated with electrostatic air cleaners is the possibility of introducing ozone into the air, which is an unacceptable risk in urban areas afflicted with air pollution. There is also the question of creating a positive space charge in a room supplied with air from an electrostatic air cleaner which is not ion-controlled, with the adverse effects this may have on asthma and hay-fever sufferers.[8]

Recently, an improved type of electrostatic air cleaner has been developed which incorporates a mechanical filter for better collection of the air-borne contaminants. This new development has many advantages but it has the same inherent disadvantage for domestic application that is inherent in all electrostatic and mechanical type filters; i.e., a regular maintenance or cleaning program is required to maintain a reasonable efficiency of the filter. In the home such a program is seldom practical and the cost of replacement filters is often excessive.

Test Results with the Use of Electric Heat

Various means of providing heat to sterilize air suggest themselves. One means is to provide a tunnellike oven through which air is passed at a controlled rate, allowing the air-borne particles to reach a temperature sufficient for their destruction.

A commercially available electric space-heating device consisting of a hollow ceramic core with an electric heating element surrounding the ceramic was selected for tests to be reported here. To be reasonably successful, it seemed essential to have incandescent heat on the inside of the ceramic core or chimney. Other means than electricity could have been used, but the latter was readily available and appeared to be the simplest where temperatures in excess of 1,000 degrees Fahrenheit (F) were desired and where the products of combustion of fuels must not contaminate or mix with the purified air. A device of this type is illustrated in Fig. 1. The ceramic core is 9 inches long by 3-inch outside diameter and $1^3/_4$-inch inside diameter. In the vertical position, approximately 10 cubic feet per minute circulate by natural convection. There is a marked advantage in having the air circulate through the ceramic chimney, wherein the heat surrounds the particles in the air, to neutralize the thermal forces that would otherwise drive the particles away from the source of heat. The open-coil electric element is covered by a charged grid to control the ions emitted from the hot element.[9]

In the tests described here, single-core Wesix ion-controlled heaters were used, some rated 1,000 watts and others 1,500 watts. The air flow averages 180 to 200 lineal feet per minute through the chimney core. The heating element, energized 30 minutes or more, operates at 1,200 to 1,500 F (measured with an optical pyrometer) and produces a temperature on the inside of the ceramic core of approximately 900 to 1,200 F.

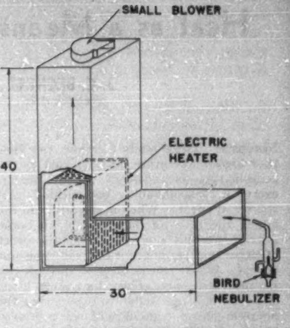

Fig. 2. Test arrangement for continuous nebulizing through electric heater

TESTS OF GERMICIDAL ACTIVITY

Three different test procedures were used:

1. Direct—in which a continuous stream of suspended organisms from a nebulizer was passed through and around the incandescent core of the heater.
2. Indirect—in an experimental room in which the concentration of the aerosolled suspended organisms could be controlled to some extent.
3. Indirect—in a residential room under natural conditions and the usual microbial content.

These three sets of tests were selected to test the effectiveness of a conventional electric room heater, as presently constructed, in the destruction of air-borne contaminants and to obtain general basic information that might lead to improvement in heater design for increased efficiency in air purification.

Direct—Using Continuous Nebulizing

In this set of experiments a Bird-type nebulizer was used (suspension in nebulizer being continuously replaced). The aerosol was directed into the open end of of an L-shaped wooden box and through a 1,000-watt electric heater in the corner of the L; see Fig. 2. Baffles were included so as to direct all of the air through and around the chimney core of the electric heating element. Provision was made to circulate air at a uniform rate through this device by means of a small fan, whether or not the heating element was energized. This test was designed to determine the degree of destruction when known particles passed through the chimney core at approximately operation speed and temperature.

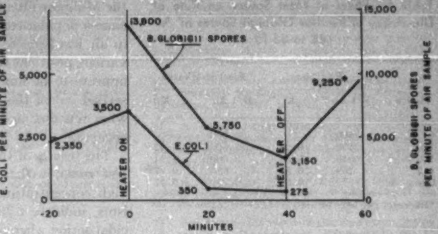
Samples of the effluent air were passed through a bubbler. This device consists of a standard glass flask arranged so that air to be sampled is drawn through a glass capillary tipped tube extending almost to the bottom of the flask and is impinged on a thin film of the solution; thereby assuring that the contaminants are retained in the solution and not carried on to the vacuum pump.[10] The volume sample is determined with the aid of a flowmeter. Experiments were conducted with viable spores (*Bacillus globigii*), vegetative bacteria (*Escherichia coli*), and an antistaphylococcus bacteriophage (Ph 65). Colony or phage counts were made in all tests by ordinary dilution and plating techniques and with the aid of a stereoscopic microscope.[11] In a few tests the relatively new Millipore filters[12] were tried with parallel results; however, under conditions of wide variation in numbers of organisms sampled, the Millipore filters were not as flexible as the usual dilution and plating technique.

In a preliminary test, plates of nutrient agar were exposed over the exhaust or chimney of the heater box. The results of this test were of interest in that a much higher colony count was obtained when the heater was in operation than when it was turned off. Later tests showed that this oddity was a result of rapid evaporation of water from the droplets coming from the nebulizer, many individual spores being set free. Since plates exposed directly to the exhaust did not give counts indicative of the total number of spores, but instead each colony developed from the spore or spores contained in separate droplets, this testing technique was entirely unsatisfactory.

This information proved useful, nevertheless; in experiments to be reported later, secondary heated air was introduced to the reflux chamber of a Wells-type nebulizer to reduce by means of evaporation the size of the aerosol droplets. This technique made it possible in experiments with bacteriophage to achieve particle size in the order of the size of the phage itself; i.e., 0.05 to 0.07 micron.

Tests using plate counts made from broth in impinger flasks (bubblers) indicated a marked reduction in numbers of viable spores as a result of the passage of spore-containing droplets through the heater. Fig. 3 illustrates typical tests and results with spores. Vegetative forms being much more susceptible to the lethal action of heat, the reduction is even greater than with the bacterial spores. *Bacillus globigii* spores are approximately 0.7 × 1.0 micron and roughly ellipsoidal in shape. They are much more heat resistant and more resistant to being nebulized and suspended in air than are vegetative bacteria. These spores proved to be the most convenient for experimental purposes. It seems reasonable to conclude that, if these spores can be destroyed by heat, mold spores of comparable size will also be destroyed, and bacteria and viruses even more rapidly.

Fig. 3. Viable counts of bacillus globigii spores and escherichia coli in aerosols (continuous spray) after passing through the heater, Fig. 2



*—Effluent air still quite warm but count approaches the original value

It should be noted that the moisture droplets containing the organisms coming from the nebulizer afford some degree of protection as the droplets go through the heater, with the result that the lethal action here is probably less effective than it might be with air-borne organisms under normal conditions. Also, the rate of airflow through the heater was slightly greater than that induced by the heater under normal use. Under the foregoing test condition, the percentage of spores in the airstream was reduced by 50 to 75 per cent, of bacteria by as much as 90 per cent, and of phage by about 99 per cent.

Indirect—Experimental Room with a High-Density Relatively Stable Microbic Population

The preceding tests gave a good indication of the potential germicidal activity that might be of practical use with a conventional type of electric heater. In the application of heat to a room it is not usual that all of the air supplied to the room be directed through the heater prior to its entry into the room. Rather, a high proportion of air is recirculated through the heat source so as to conserve heat, and it is problematical whether all of the air in the room will find its way through the heater or whether portions will be stagnant in corners of the room. Thus, purification by this means is to a great degree a dilution process whereby the content of microbes in the air is greatly reduced but never reaches zero. With this in mind, a second series of tests were conducted in a relatively small room, 350 cubic feet, in which the heater was permitted to circulate air in the normal way. In addition, a relatively high air-borne population of bacterial spores was aerosolled into the test room, with the use of a Wells-type nebulizer,[13] and the suspension was allowed to stabilize by standing.

In these tests, a 1,500-watt heater was selected with the thermostat either bypassed or set at its highest position, approximately 95 F. This was done because a 1,500-watt electric heater is a more popular size for home heating; and it produces higher temperatures than the smaller capacity heaters. Its thermostat was set high to keep the heater energized a reasonable length of time, considering the small size of the room. Control tests were performed under identical conditions with an electrically heated hot-water radiator to provide approximately the same room temperatures as obtained with the test heater itself.

The spores were sprayed into the room late in the afternoon so that a relatively stable population could develop over a 16-hour period. The rate of decrease in numbers of stabilized air-borne spores can be expressed by the equation

$$K = 2.303/t \log B_0/B_t$$

where B_0 is the number of viable organisms at the beginning of the time interval t and B_t is the number at the end. The velocity constant for the die-away was around 0.1 in the stabilized suspensions at 72 F; and about 0.8 to 0.9 in the higher temperature range when using the hot-water radiator. The calculated velocity constants were much higher when the radiant electric heater was in operation, being in the neighborhood of 1.25 to 1.50.

In similar tests, lower average room temperatures, 82 to 85 degrees, were maintained with the aid of a thermostat

Table I. Effect of Heat Source on Rate of Die-Away of Bacillus Globigii Spores in Air (82 to 85 F)

	Radiator		Electric Heater	
Hours	B/1 Air*	K	B/1 Air*	K
0	3800		20,000	
1.5	2500	0.28	10,600	0.42
3.0	1040	0.58	2,000	1.11
4.5	289	0.85	630	0.77
0 to 4.5		0.57		0.77

*Bacteria per liter of air.

control. *K* values near 1.0 were noted when using the electric heater as compared with 0.4 to 0.5 with the control radiator. In this test, the electric heater operated for only a few minutes at a time, the hollow core of the heater never reaching the maximum temperature.

Room temperature in excess of 80 F was found to be particularly detrimental to vegetative microbes but increased the rate of die-away to a lesser degree with *Bacilius globigii* spores. Use of the hot-water radiator for controls to obtain room temperatures equal to those observed with the electric heater removed any doubt about the results of this series of tests; see Table I.

It should be noted that considerable difficulty was experienced in maintaining stable suspension of relatively high microbic density. Air turbulence such as from a fan or air conditioner rapidly reduced numbers of suspended spores or vegetative cells. This is not to suggest that an air conditioner or fan has lethal effects but rather that, in an artificial environment as used here, these disturbing factors caused the spore-containing droplets or particles from the nebulizer to precipitate or impinge onto solid objects that might be encountered. These organisms are apt to become a source of secondary aerosols and lead to confusion in test procedure. Care had to be taken to maintain air movement in the test room at the level that might be encountered in the home. A commercial air conditioner (for the purpose of maintaining a room temperature of 72 degrees at all times with the heater in operation) could not be used in this experiment for the reason cited in the foregoing.

The percentages of spores settling on nutrient agar exposed in petri dishes in the test room were of a low order and of the same magnitude for either source of heat. There was less consistency in the results obtained with spores settling on petri dishes than with colony counts obtained from air samples either passed through broth in the bubbler or through the Millipore filters. This was interesting since a popular test for germicidal activity in air has been to expose petri dishes at various positions in a room. Such a test appears to be limited; it tells only what settled out of the air by gravity and not what remains air-borne to be inhaled by occupants.

The results of these tests in the special test room, with the use of a relatively high concentration of aerosolized organisms, indicate a highly significant sporicidal action when an electric heater of the open-coil radiant type is used as compared with a low temperature source, i.e., a hot-water radiator. The conditions being impractical for extrapolation to the home, it was decided to extend the tests by sampling air in a typical residence.

Indirect—In a Residence Room Under Natural Conditions

Tests in a home were conducted on widely different days and in different rooms but under normal living conditions. The numbers of bacteria per unit volume of air showed considerable variation, though the numbers were never high, but they were quite consistent in replicate samples collected the same day. This low density of organisms increases the error of measurement, requiring a large number of samples. A brief summary of these results has been reported.[14] A complete description follows:

Several samples of air were tested prior to the 1,500-watt Wesix heater being turned on. These agreed closely with each other for a given day, though large samples, up to 100 liters of air, were required. Results are illustrated in Table II. The percentage reductions (including higher fungi developing on incubation for 72 hours) observed after 1 hour of automatic heater operation (69 to 72 F) ranged from 46 to 56 per cent and in the following hour 30 to 80 per cent. Position of the heater in the room and the different air circulation patterns established probably account for the wide variations observed in longer tests.

Measurements in the home presented many difficulties primarily because of the low density of organisms as compared with the previous artificial conditions. As a precaution, three different methods of sampling were used. These were as follows:

1. Filtration of a measured volume of air through a Millipore filter, moistening the filter with nutrient broth, and transferring the filter to a nutrient pad for incubation.

†Numbers settling on agar in petri dish in 15 minutes.

‡Wall-type heater instead of floor-model heater.

2. Filtration of a measured volume of air through broth in an impinger vessel and filtering the broth through a Millipore filter, the filter then being transferred to a nutrient pad.

3. Same as 2 except that aliquots were transferred to petri dishes and mixed with nutrient agar before incubation.

The Millipore filter was advantageous for filtering because of the small number of organisms present, but this was offset to a considerable degree because of the wide variations found in different rooms and at different times of the year (experiments in the home were conducted in December, January, and March), and the Millipore filter does not permit subsequent dilution to reduce numbers. In general, the bubbler technique of impingement in solution proved to be the most convenient method of obtaining an air sample.

Conclusions

Electric heaters of the incandescent type will reduce the microbial content of room air during the heating season by as much as 50 per cent per hour or better. The results of the direct aerosolation through and around the electrically heated ceramic core indicated that most of the destructive effect takes place inside the chimney core. Velocity of the particles moving through the core, temperature of the core, and the mass of the organic particles are principal factors. A longer period of exposure to the intense heat by either increasing the ceramic temperature or the length of the ceramic would improve performance. It was observed that very little destruction occurred in the air directed over the exterior surfaces of the ceramic core or the heating element. This is attributed to the fact that thermal forces acted to direct the particulate matter away from the hot body before destruction could be effected. It appears feasible that an electrostatic field could be used to overcome this thermal force and, thereby, enhance destruction through better utilization of hot surfaces on the exterior of the core.

For year-around air purification, a device using incandescent electric elements in combination with an electrostatic field to improve the efficiency, and with a cooling device to control the final air temperature, appears feasible, though perhaps not presently attractive economically.

The Pulse Stretch Coupling Circuit

H. W. PATTON
ASSOCIATE MEMBER AIEE

Synopsis: This paper describes a new coupling circuit applicable to both half-wave and full-wave magnetic amplifiers, particularly those amplifiers simultaneously requiring fast time response and large power gains. The pulse stretch technique uses a pulsating bias signal derived from an external supply to block the power winding of the reactor during reset. This blocking action permits free core control yielding an amplifier with an improved figure of merit.

General

MODERN high-performance equipments frequently require magnetic amplifiers having both fast response and large power gains. These requirements are typical of aircraft hydraulic control valves, instrument positioning servos, and other similar devices.

An early form of high-speed magnetic amplifier was reported by Ramey,[1] as shown in Fig. 1.

When operated in class B, E_b is adjusted to cause minimum current flow in the power circuit. Control current provided by E_c flows in mixing resistor R_m during the core reset cycle. This added current resistance drop through R_m reduces the net reset applied to the core, causing it to saturate earlier during the next firing cycle. E_c may be alternating current, direct current, or pulses, but to be most effective this control signal should match the wave form of E_b. To cause operation and cutoff with $E_c = 0$, E_b, R_m, or the reset winding turns may be adjusted. Usually, E_b is chosen with relation to the available E_c. If E_c is pulsed, as from a preceding magnetic amplifier, and E_b and E_p are sinusoidal, difficulties may be experience in achieving full control of the output core.

Another amplifier circuit reported by Ramey[1,2] is depicted in Fig. 2. This amplifier operates at full output with zero control. As E_c increases, assuming proper phase relationships, core reset is increased, gradually reducing the amplifier output.

For optimum operation and full control range, E_c should be of the same wave form as E_p and under maximum reset conditions the instantaneous value of E_c times the reactor turns ratio essentially equals E_p. If E_c exceeds this value, the voltage applied to the power winding rectifier will reverse, causing conduction in the power winding. This reflects a low impedance to the control winding compared to normal values of core-magnetizing current. For purposes of this paper the phenomenon just described will be termed "oversetting."

If E_c is pulsed, as from a preceding magnetic amplifier, difficulties may be experienced in obtaining proper amplifier control, as will be explained later.

For a maximum performance amplifier the type and amount of core material should be selected according to the available signal energy. For ordinary amplifiers this poses no particular problem. It is possible to construct an amplifier having an optimum quantity of core material so that the input energy under full signal conditions is just adequate to supply the B-H volume iron loss and the small copper loss. If the input energy is exceedingly small, the volume of iron called for may be less than 0.0001 cubic inch. Unfortunately, while such a design is constructable its manufacture is quite inconvenient and impractical. A typical reactor of this size may need 10,000 turns of no. *46* wire. If a larger core volume than the indicated amount is used, the input energy will be insufficient to control the core over more than a small portion of the firing angle. Here is the crux of the problem. Assuming the input energy is very small, so that it is impractical to use a core having an ideal configuration, and a larger core is used, the input energy is found only sufficient to control the core over a small part of its normal 180-degree range. This means that the output signal from the first core is a spike which occurs during the last part of the power cycle. If coupling the output from this core to another half cycle stage is attempted, it is discovered that the bias voltage times turns ratio requirement must still be satisfied. Matching on a proper voltage basis reveals that the output stage is controlled only over the same small firing angle as the input core. On the other

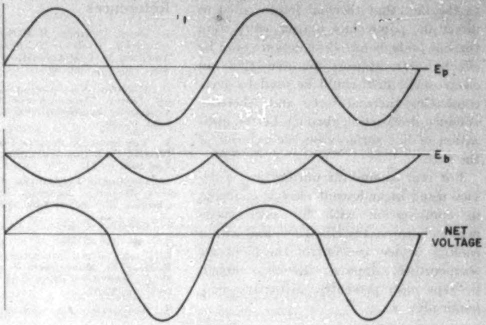

Fig. 4 (above right). Pulse stretch amplifier wave forms

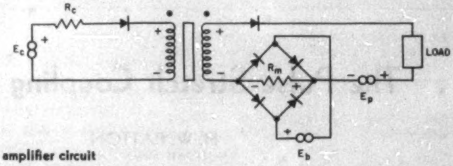

Fig. 5. Pulse stretch amplifier circuit

hand, if achieving a step-up ratio is tried, control energy is lost by circulation in the power winding through overset.

If a very large amount of control energy is available it may be possible to overpower the core despite this circulating current in the power winding. Unfortunately, these operating conditions do not yield an amplifier with the maximum possible power gain.

Cousequently, some form of device is needed to effectively "stretch" the output pulse from the first reactor so that it will match the wave form of the second. Various techniques have been tried to accomplish this.

Storage elements such as capacitors or inductors can be used to absorb the energy during the firing interval of the first reactor and deliver it a short time later to the output core, but at a much slower rate, so that the pulse will be more effective. Unfortunately, it is difficult to store the energy and in most practical cases much of it is delivered to the output core, not during its reset cycle but during its firing cycle, thereby wasting it. Consequently, the amplifier's figure of merit is substantially reduced.

Rather than devise lossless storage elements, the oversetting problem may be easily solved by opening the power winding with a mechanical switch during the reset interval. While this is technically possible and has been accomplished experimentally, it is not considered desirable for long life.

Diode ring modulators or transistors may be used to replace the mechanical switch but require several expensive components and have other undesirable characteristics.

Proposed Solution

Since all that is required is some means to block the signal in the power circuit during reset of the core, it may be observed by tracing out the polarities in Fig. 2, that this can be accomplished by inserting a counter voltage in the power circuit, as shown in Fig. 3.

This circuit is identical to Fig. 2 except that a half-wave pulsating signal has been placed in the power circuit to increase the blocking voltage applied to the power winding rectifier during core reset. With this blocking bias it is possible to increase the instantaneous rate of reset, i.e., if the blocking bias voltage is three times the normal power winding voltage, the core may be reset at a rate equal to four times normal. This means a limited range of control signal may be stretched, into one which is effectively much larger. Thus, with the power winding blocked, we are free to readjust the turns ratio of *SR* in Fig. 3 to obtain maximum energy transfer to the core. This permits much larger power gains per stage with no penalty in increased time response; hence, an increased amplifier figure of merit can be readily obtained.

There are numerous convenient methods of generating the signal for the stretch bias. One of the most convenient is to superimpose an a-c signal on a fully rectified d-c signal as shown in Fig. 4.

During the first half-cycle E_b subtracts from E_p reducing its value by one-third. During the next half-cycle E_b adds to the E_p thereby supplying twice the net blocking voltage to the rectifier.

With this arrangement E_p must be increased to compensate for voltage cancellation by E_b during the firing cycle. Since the power winding rectifier is now receiving the extra blocking voltage, the instantaneous control signal may be doubled without encountering overset difficulties. Fig. 5. shows a typical pulse stretch amplifier using this method.

Stretch may be applied up to five times the normal E_p value with favorable results. Increased stretch ratios seem to yield little improvement. Problems encountered are:

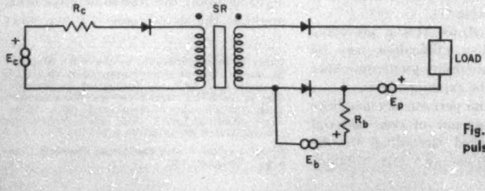

Fig. 3. Simplified pulse stretch amplifier circuit

1. The power winding rectifier leakage increases, resulting in uncontrolled core reset and loss of control range.

2. This leakage causes temperature drift problems.

3. The effective core B-H volume product increases. This is believed to be caused by an increase in the instantaneous value of core H caused by eddy current losses.

4. Energy lost in R_m increases.

These problems are all minimized by operating at stretch ratios of from 3 to 5.

Pulse stretch circuitry does not appear to be too practical for output stages. Iron volumes can usually be optimized, eliminating the need for pulse stretch compensation.

Conclusions

Pulse stretch circuits are most applicable to high-performance low-level stages which do not receive optimum input wave forms or where it is inconvenient to optimize core volumes.

The pulse stretch technique can be applied to many varieties of magnetic amplifiers. Its operation is simple, straightforward, and can be readily calculated.

It is hoped that pulse stretch circuits will afford another useful tool with which to attack difficult design problems.

Temperature Stabilization of Transistor Amplifiers

L. M. VALLESE
ASSOCIATE MEMBER AIEE

Synopsis: A novel method of analysis of the thermal behavior of transistor amplifiers is developed by introducing the temperature incremental equations of the transistor and of its associated d-c network. Design formulas for prescribed thermal stability, and in particular for the case of thermistor compensation, are derived. Experimental verifications of the theory are included.

THE DESIGN of transistor amplifiers for thermal stability is usually performed on the basis of the equations expressing the derivatives (or the logarithmic derivatives) of collector current and voltage with respect to temperature. Shea[1] has taken into account the temperature dependence of I_{co} (open input-collector current), Tate[2] has added that of the collector resistance and, recently, Lin and Barco[3] have considered the temperature dependence of the input conductance of the transistor. In general, the expressions of the I_c and V_c derivatives obtained for certain fundamental types of d-c circuit configurations[4] are used directly for the thermal stability design. Temperature compensation can also be obtained with the use of thermistors and other temperature-dependent elements.

In the following, the problem of the temperature analysis of transistor amplifiers is approached with a different procedure; it is based on the observation that the rates of change of the input and output currents and voltages satisfy a set of linear equations obtained from the d-c characteristics of the transistor with an incremental procedure similar to that used to derive the so-called "small signal analysis" equations. The consideration of these "temperature incremental" equations provides an accurate and general method of thermal analysis and, in particular, permits the design of circuits containing thermistors. In the following, the simplifying assumption is made that all temperature rates of change are independent of temperature in the range of interest.

Temperature Incremental Equations

In general, if the transistor d-c characteristics are represented with the equations (referred to common base configuration)

$$I_e=f_1(V_{eb},\ V_{cb}) \qquad (1)$$
$$I_c=f_2(V_{eb},\ V_{cb})$$

differentiation with respect to T (absolute temperature) gives

$$\frac{dI_e}{dT}=\frac{\partial f_1}{\partial T}+\frac{\partial f_1}{\partial V_{eb}}\frac{dV_{eb}}{dT}+\frac{\partial f_1}{\partial V_{cb}}\frac{dV_{cb}}{dT} \qquad (2)$$
$$\frac{dI_c}{dT}=\frac{\partial f_2}{\partial T}+\frac{\partial f_2}{\partial V_{eb}}\frac{dV_{eb}}{dT}+\frac{\partial f_2}{\partial V_{cb}}\frac{dV_{cb}}{dT}$$

Since the coefficients $\partial f_1/\partial V_{eb}$, $\partial f_1/\partial V_{cb}$, $\partial f_2/\partial V_{eb}$, and $\partial f_2/\partial V_{cb}$ are computed at the quiescent point of operation, they are equal to the corresponding small signal analysis coefficients, when the transistor amplifier is operating in class A. In this case, using primes to indicate temperature derivatives and letting $I_{eT}' = \partial f_1/\partial T$, $I_{cT}' = \partial f_2/\partial T$, equations 2 are written

$$I_e'=I_{eT}'+g_{ee}V_{eb}'+g_{ec}V_{cb}' \qquad (3)$$
$$I_c'=I_{cT}'+g_{ce}V_{eb}'+g_{cc}V_{cb}'$$

When the transistor does not operate in class A, equations 2 should be used instead of 3. Equations 2 and 3 are the desired temperature incremental equations of the transistor; for class A operation their equivalent circuit representation shown in Fig. 1, case A, may be considered obtained from the small signal equivalent circuit with the introduction of current sources I_{eT}', I_{cT}'.

Shockley, et al.,[5] have analyzed the temperature dependence of the d-c transistor equations. Letting, for the common base configuration

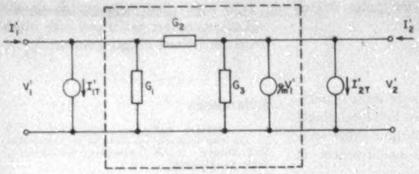
$$I_e=\frac{G_{ee}}{\Lambda}(e^{\Lambda V_{eb}}-1)+\frac{G_{ec}}{\Lambda}(e^{\Lambda V_{cb}}-1) \qquad (4)$$
$$I_c=\frac{G_{ce}}{\Lambda}(e^{\Lambda V_{eb}}-1)+\frac{G_{cc}}{\Lambda}(e^{\Lambda V_{cb}}-1)$$

where $\Lambda = +q/kT$ for p-n-p and $-q/kT$

Paper 56-276, recommended by the AIEE Solid State Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted November 30, 1955; made available for printing, March 26, 1956.

L. M. VALLESE is with Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

This work was performed at the Microwave Research Institute of the Polytechnic Institute of Brooklyn, under a Contract sponsored by the Office of Naval Research. The assistance of B.S. Fabricant in obtaining the experimental results of Figs. 3 and 5 is gladly acknowledged by the author.



Case A—$G_1 = g_{ee} + g_{ec}$, $G_2 = -g_{ec}$, $g_m = g_{ce} - g_{ec}$, $G_3 = g_{cc} + g_{ec}$

Case B—$G_1 = g_{bb} + g_{bc}$, $G_2 = -g_{bc}$, $g_m = g_{cb} - g_{bc}$, $G_3 = g_{cc} + g_{bc}$

Fig. 1. Temperature incremental equivalent circuit of transistor

for n-p-n transistors $G_{ce} = G_{ec}$, it is found that the G coefficients are proportional to σ_i^2/σ_n or σ_i^2/σ_n, where σ_i, σ_p, and σ_n are respectively the intrinsic, the p-type, and the n-type conductivities. Since

$$\sigma_i^2 \propto \exp(-E_g/kT)$$

where E_g is the energy gap, and σ_p, σ_n are proportional to $(T)^{-3/2}$ at room temperature, then

$$\frac{\partial}{\partial T}\left(\frac{G}{\Lambda}\right) \propto \frac{d}{dT}\left[T^{3/2}\exp(-E_g/kT)\right] = \left(\frac{5}{2T}+\frac{E_g}{kT^2}\right)\left[T^{3/2}\exp(-E_g/kT)\right] \quad (5)$$

In other words, at room temperature and with $E_g = 0.72eV$ for germanium, the G coefficients increase

$$\left(\frac{5}{2T}+\frac{E_g}{kT^2}\right)\% \cong 10\%$$

per K (degree Kelvin).

Accordingly, the terms I_{eT}', I_{cT}' in equations 3 become respectively

$$I_{eT}' \cong -0.1\left(\frac{G_{ee}+G_{ec}}{\Lambda}\right)+\left(\frac{0.1}{\Lambda}-\frac{V_{eb}}{T}\right)\times G_{ee}\epsilon^{\Lambda V_{eb}}+\left(\frac{0.1}{\Lambda}-\frac{V_{cb}}{T}\right)G_{ec}\epsilon^{\Lambda V_{cb}} \quad (6)$$

$$I_{cT}' \cong -0.1\left(\frac{G_{ce}+G_{cc}}{\Lambda}\right)+\left(\frac{0.1}{\Lambda}-\frac{V_{eb}}{T}\right)\times G_{ce}\epsilon^{\Lambda V_{eb}}+\left(\frac{0.1}{\Lambda}-\frac{V_{cb}}{T}\right)G_{cc}\epsilon^{\Lambda V_{cb}}$$

Usually these may be approximated as follows:

$$I_{eT}' \cong \left(\frac{0.1}{\Lambda}-\frac{V_{eb}}{T}\right)G_{ee}\epsilon^{\Lambda V_{eb}}$$

$$I_{cT}' \cong \left(\frac{0.1}{\Lambda}-\frac{V_{eb}}{T}\right)G_{ce}\epsilon^{\Lambda V_{eb}} \quad (7)$$

For example, using the values of d-c conductance coefficients published by Giacoletto[6] for a p-n-p alloy transistor at 298 K

$G_{ee} = 75.2$ micromhos, $G_{ec} = G_{ce} = -70.5$ micromhos, $G_{cc} = 137$ micromhos

$\Lambda = 38.8\ V^{-1}$, $V_{eb} = 0.17\ V$, $V_{cb} = -6V$, $I_e = 1$ milliampere

one finds

$$I_{eT}' \cong 111\times 10^{-6}\ A \text{ per K}$$

$$I_{cT}' \cong -105\times 10^{-6}\ A \text{ per K} \quad (8)$$

The temperature incremental equations for the common emitter configuration may be derived similarly from the corresponding d-c characteristics

$$I_b = \frac{1}{\Lambda}(G_{ee}+G_{ec}+G_{ce}+G_{cc}) - \frac{1}{\Lambda}\left[G_{ee}+G_{ec}+(G_{ec}+G_{cc})\epsilon^{\Lambda V_{ce}}\right]\epsilon^{-\Lambda V_{be}} \quad (9)$$

$$I_c = \frac{-1}{\Lambda}(G_{ce}+G_{cc})+\frac{1}{\Lambda}(G_{ce}+G_{cc}\epsilon^{\Lambda V_{ce}})\epsilon^{-\Lambda V_{be}}$$

Of course, the equations may be obtained more simply from equations 2 or 3, letting $I_{bT}' = -I_{eT}' - I_{cT}'$. For class-$A$ operation they are written

$$I_b' = I_{bT}' + g_{bb}V_{be}' + g_{bc}V_{ce}' \quad (10)$$

$$I_c' = I_{cT}' + g_{cb}V_{be}' + g_{cc}V_{ce}'$$

where

$$g_{bb} = g_{ee}+g_{ec}+g_{ce}+g_{cc},\quad g_{bc} = -g_{ec}-g_{cc},\quad g_{cb} = -g_{ce}-g_{cc},$$

and

$$I_{bT}' \cong \frac{0.1}{\Lambda}(G_{ee}+G_{ec}+G_{ce}+G_{cc}) - \left(\frac{0.1}{\Lambda}-\frac{V_{eb}}{T}\right)(G_{ee}+G_{ce})\epsilon^{\Lambda V_{eb}} - \left(\frac{0.1}{\Lambda}-\frac{V_{cb}}{T}\right)(G_{ec}+G_{cc})\epsilon^{\Lambda V_{cb}}$$

I_{cT}' has been given in equation 6. The equivalent circuit representation is shown in Fig. 1, case B. With the data of the example previously considered, one finds

$$I_{bT}' \cong -6.8\times 10^{-6}\ A \text{ per K} \quad (11)$$

$$I_{cT}' \cong -105\times 10^{-6}\ A \text{ per K}$$

In practice, the actual transistor characteristics differ from equations 4 because of the presence of extrinsic elements, such as base-spread and collector-leakage resistances. Accordingly, equations 4 should be modified to include these additional elements. For example, on account of the base spread resistance r_{bb}', the quantities V_{eb} and V_{cb} in equation 4 should be replaced with $V_{eb}+I_br_{bb}'$ and $V_{cb}+I_br_{bb}'$ respectively. Another less rigorous procedure consists in replacing equations 4 with experimentally determined characteristics, provided these may be expressed analytically with good approximation. Fig. 2 represents typical input and output characteristics of a p-n-p common emitter transistor. For the linear region of interest they may be represented approximately with the equations

$$I_b = g_{bb}(V_{be}-V_{be}^\circ)+g_{bc}(V_{ce}-V_{ce}^\circ) \quad (12)$$

$$I_c = I_{coe}+\alpha_{cb}I_b+g_{cc}^\circ(V_{ce}-V_{ce}^\circ)$$

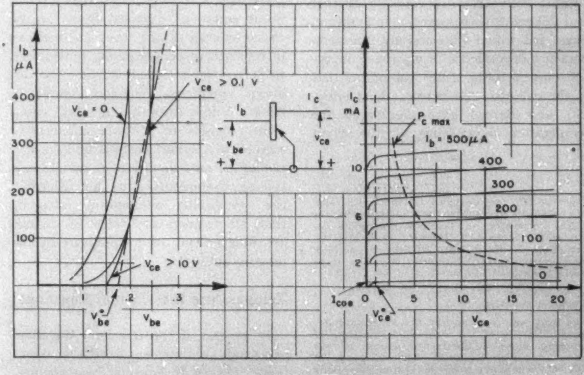


Fig. 2. Typical input and output characteristics of common emitter transistor

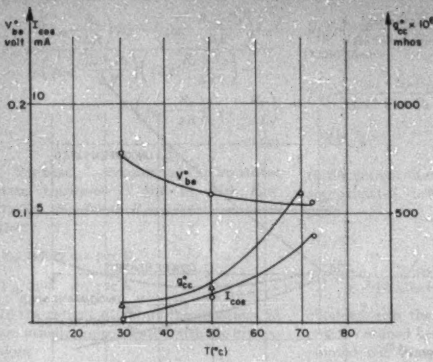

Fig. 3. Summary of thermal behavior of a common emitter transistor

where V_{be}°, V_{ce}° are shown in Fig. 2, and $I_{cos}=(1+\alpha_{cb})I_{cob}$ is the collector current for $I_b=0$, V_{ce}°. Note that g_{ce}° is the output conductance with open input circuit and is equal to $g_{ce}-\alpha_{cb}g_{bc}$. From equations 12 the following expressions of $I_{bT}'=\partial I_b/\partial T$, $I_{cT}'^*=\partial I_c/\partial T$ are derived

$$I_{bT}'=\frac{\partial g_{bb}}{\partial T}(V_{be}-V_{be}^\circ)-g_{bb}\frac{\partial V_{be}^\circ}{\partial T}+\frac{\partial g_{bc}}{\partial T}(V_{ce}-V_{ce}^\circ) \quad (13)$$

$$I_{cT}'^*=\frac{\partial}{\partial T}I_{coe}+\frac{\partial \alpha_{cb}}{\partial T}I_b+\frac{\partial g_{ce}}{\partial T}(V_{ce}-V_{ce}^\circ)$$

In first approximation these may be written

$$I_{bT}'\cong\frac{\partial g_{bb}}{\partial T}(V_{be}-V_{be}^\circ)-g_{bb}\frac{\partial V_{be}^\circ}{\partial T}$$
$$(14)$$
$$I_{cT}'^*\cong\frac{\partial}{\partial T}I_{coe}+\frac{\partial g_{ce}^\circ}{\partial T}(V_{ce}-V_{ce}^\circ)$$

It is noted that

$$I_{cT}'^*=\left(\frac{\partial I_c}{\partial T}\right)_{I_b,\,V_{ce}\,\mathrm{const}}$$
$$\neq I_{cT}'=\left(\frac{\partial I_c}{\partial T}\right)_{V_{be},\,V_{ce}\,\mathrm{const}}$$

In fact, $I_{cT}'=I_{cT}'^*+\alpha_{cb}I_{bT}'$.

The temperature incremental equations derived from equations 12 are

$$I_b'=I_{bT}'+g_{bb}V_{be}'+g_{bc}V_{ce}'$$
$$(15)$$
$$I_c'=I_{cT}'^*+\alpha_{cb}I_b'+g_{ce}^\circ V_{ce}'$$

They may be written as in equation 10 provided

$$I_{cT}'=I_{cT}'^*+\alpha_{cb}I_{bT}',\quad g_{cb}=\alpha_{cb}g_{bb}$$
$$(16)$$
$$g_{ce}=g_{ce}^\circ+\alpha_{cb}g_{bc}$$

In Fig. 3 are summarized the results of an experimental investigation of the thermal behavior of a common emitter p-n-p alloy transistor. With reference to the operating point $V_{be}=-0.2V$, $I_b=-60\mu A$, $V_{ce}=-6V$ at 30 degrees centigrade, one finds

$g_{bb}=1.35\times10^{-3}$ mhos,
$g_{bc}=-0.5\times10^{-6}$ mhos,
$g_{ce}^\circ=70$ micromhos

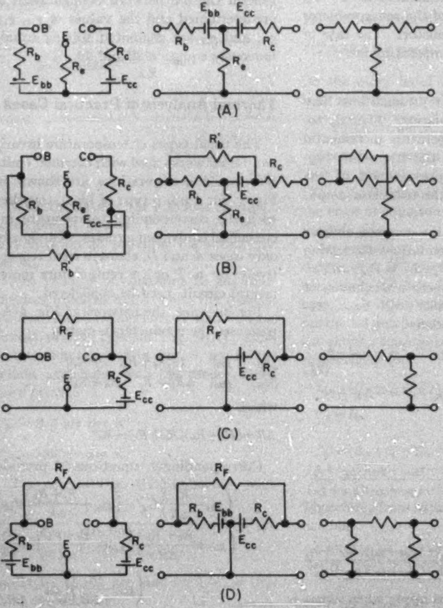

Fig. 4 (left). Temperature invariant d-c bias networks for class-A transistor amplifiers

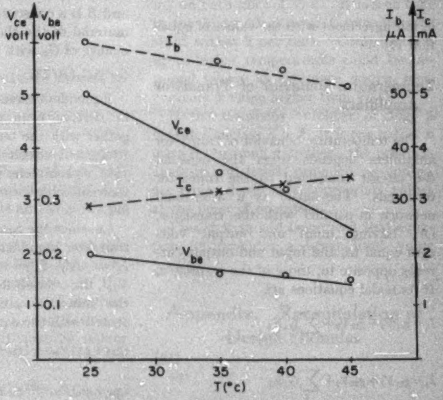

Fig. 5 (above). Thermal variations of V_{be}, V_{ce}, I_c, and I_b, in a common emitter-transistor amplifier

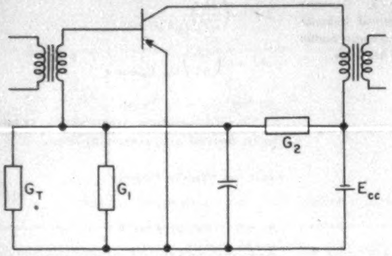

Fig. 6. Thermistor-compensated common emitter-transistor amplifier

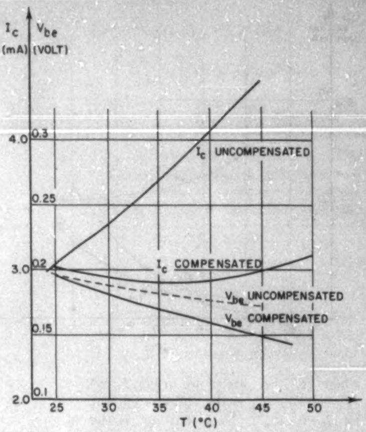

Fig. 7. Thermal behavior of the circuit of Fig. 6: (a) with thermistor, (b) with ohmic resistor replacing thermistor

$$\alpha_{cb}=40, \quad V_{be}{}^{\circ}=-0.155\ V,\ I_{coe}=-0.1 \text{ milliampere}$$

$$V_{ce}{}^{\circ}=-1\,V,\ \frac{\partial g_{bb}}{\partial T}\cong 0,$$

$$\frac{\partial V_{be}{}^{\circ}}{\partial T}\cong +0.0018\ V \text{ per K} \quad (17)$$

$$\frac{\partial I_{coe}}{\partial T}\cong 0.1 I_{coe},\ \frac{\partial g_{ec}{}^{\circ}}{\partial T}\cong 0.1\ g_{ec}{}^{\circ}$$

Therefore, from equations 14

$$I_{bT}'\cong -2.44\times 10^{-6}\ A \text{ per K}$$

$$I_{cT}'^{*}\cong -45\times 10^{-6}\ A \text{ per K} \quad (18)$$

$$I_{cT}'\cong -142.6\times 10^{-6}\ A \text{ per K}$$

in fair agreement with the values of equation 11.

Temperature Behavior of Transistor Amplifiers

The temperature behavior of transistor amplifiers depends upon the external d-c circuit connected to the transistor terminals. The latter is a 3-terminal network in parallel with the transistor, i.e., having input and output voltages equal to, and input and output currents opposite to, those of the transistor. If its nodal equations are

$$I_1=g_{11}V_1+g_{12}V_2+\sum_i G_iE_i$$
$$(19)$$
$$I_2=g_{21}V_1+g_{22}V_2+\sum_j G_jE_j$$

the corresponding temperature incremental equations are written

$$I_1'=g_{11}V_1'+g_{12}V_2'+\theta_1$$
$$(20)$$
$$I_2'=g_{21}V_1'+g_{22}V_2'+\theta_2$$

In equations 20 θ_1 and θ_2 are respectively the partial derivatives of I_1 and I_2 with respect to temperature. If the network is temperature invariant, $\theta_1=\theta_2=0$; if the network in parallel with the transistor, i.e., contains thermistors (in particular p-n junction diodes), θ_1 and θ_2 are computed on the basis of the temperature dependence of their conductances. This is approximately of the type[7]

$$G_T\cong G_{T_0}e^{B/T_0}e^{-B/T}$$

where G_{T_0} is the conductance at $T=T_0$, and B is a constant of the semiconductor material of the thermistor. The rate of change of G_T with temperature is

$$G_T'\cong G_T(B/T^2)$$

Equivalent circuit representations may be derived from equations 20 and, together with the temperature incremental equivalent circuit of the transistor, provide a complete representation of the thermal behavior of the transistor amplifier.

Consider the case of a common emitter transistor amplifier, equations 10, letting $I_1'=-I_b'$, $I_2'=-I_c'$, $V_1'=V_{be}'$, $V_2'=V_{ce}'$, the over-all temperature behavior of the transistor amplifier will be represented with the equations

$$(g_{bb}+g_{11})V_{be}'+(g_{bc}+g_{12})V_{ce}'=-I_{bT}'-\theta_1$$
$$(21)$$
$$(g_{cb}+g_{21})V_{be}'+(g_{cc}+g_{22})V_{ce}'=-I_{cT}'-\theta_2$$

Then

$$V_{be}'=\frac{(g_{bc}+g_{12})(I_{cT}'+\theta_2)-(g_{cc}+g_{22})(I_{bT}'+\theta_1)}{(g_{bb}+g_{11})(g_{cc}+g_{22})-(g_{bc}+g_{12})(g_{cb}+g_{21})}$$
$$(22)$$
$$V_{ce}'=\frac{(g_{cb}+g_{21})(I_{bT}'+\theta_1)-(g_{bb}+g_{11})(I_{cT}'+\theta_2)}{(g_{bb}+g_{11})(g_{cc}+g_{22})-(g_{bc}+g_{12})(g_{cb}+g_{21})}$$

The same equations apply when equations 15 instead of 10 are given, provided the relations 16 are used. From equations 22 and equations 10 or 20, the values of I_b', I_c' follow.

Equations 22 may be used for the design of temperature-stabilized amplifiers, with prescribed values of V_{be}', V_{ce}' (usually I_c' and V_{ce}' are prescribed). In general the d-c network configuration is predetermined and the values of g_{11}, g_{12}, g_{21}, and g_{22} are computed solving simultaneously equation 22 and 19.

Thermal Analysis of Practical Cases

The usual types of temperature-invariant d-c networks used with common emitter class-*A* configurations are shown in Fig. 4 (for a p-n-p type of bias), together with the corresponding temperature incremental equivalent circuits. Obviously only cases *A* and *D*, characterized respectively by a *T* or a π temperature incremental circuit, need be considered.

For instance, the network of Fig. 4(A) possesses the conductance matrix

$$\left\|\begin{matrix} g_{11} & g_{12} \\ g_{21} & g_{22}\end{matrix}\right\| = \frac{1}{\Delta R}\left\|\begin{matrix} R_e+R_c, & -R_e \\ -R_e & R_e+R_b\end{matrix}\right\|$$

where

$$\Delta R=(R_e+R_b)(R_e+R_c)-R_e^2$$

Correspondingly, equations 22 provide

$$V_{be}'=\frac{\left(g_{bc}-\frac{R_e}{\Delta R}\right)I_{cT}'-\left(g_{cc}+\frac{R_e+R_b}{\Delta R}\right)I_{bT}'}{\left(g_{bb}+\frac{R_e+R_c}{\Delta R}\right)\left(g_{cc}+\frac{R_e+R_b}{\Delta R}\right)-\left(g_{bc}-\frac{R_e}{\Delta R}\right)\left(g_{cb}-\frac{R_e}{\Delta R}\right)}$$

$$V_{ce}'=\frac{\left(g_{cb}-\frac{R_e}{\Delta R}\right)I_{bT}'-\left(g_{bb}+\frac{R_e+R_b}{\Delta R}\right)I_{cT}'}{\left(g_{bb}+\frac{R_e+R_c}{\Delta R}\right)\left(g_{cc}+\frac{R_e+R_b}{\Delta R}\right)-\left(g_{bc}-\frac{R_e}{\Delta R}\right)\left(g_{cb}-\frac{R_e}{\Delta R}\right)} \tag{23}$$

For example, considering the transistor data, equations 17 and 18, with $R_b=3{,}000\Omega$, $R_e=200\Omega$, $R_c=5{,}000\Omega$, one finds that

$V_{be}'\cong 2.22$ mv per K

$V_{ce}'\cong 95$ mv per K

In the current literature the equations 23 are usually approximated with the expressions

$$V_{be}'\cong 0$$

$$V_{ce}'\cong\frac{-I_{coe}'}{g_{ce}^{\circ}+\alpha_{cb}\frac{R_e}{\Delta R}+\frac{R_e+R_b}{\Delta R}} \tag{24}$$

obtained, assuming $I_{bT}'=0$, $V_{be}'=0$, $I_{cT}'=I_{coe}'$ and substituting I_b' of equations 15 with the value provided by the first of equations 20. Note that, due to the approximations involved, the result equation 24 does not represent a unique solution; as a matter of fact from equation 23 with the same assumptions one obtains the following:

$$V_{ce}'=\frac{-I_{coe}'}{g_{ce}^{\circ}+\alpha_{cb}g_{bc}+\frac{R_e+R_b}{\Delta R}-\frac{\left(g_{bc}-\frac{R_e}{\Delta R}\right)\left(g_{cb}-\frac{R_e}{\Delta R}\right)}{g_{bb}+\frac{R_e+R_c}{\Delta R}}} \tag{25}$$

With the data of the previous example, equations 24 provide $V_{ce}'=13$ mv per K and equation 25 provides $V_{ce}'=15.2$ mv per K.

The validity of equations 23 has been checked experimentally using the transistor described in equations 17 and 18 in a circuit of the type in Fig. 4(A). The results, summarized in Fig. 5, are in excellent agreement with the theory, since they provide

$V_{be}'=2.5$ mv per K

$V_{ce}'=132$ mv per K

The case of Fig. 4(D) is solved, with equations

$$\left\|\begin{matrix} g_{11} & g_{12} \\ g_{21} & g_{22}\end{matrix}\right\|=\left\|\begin{matrix} G_b+G_P, & -G_P \\ -G_P & G_c+G_P\end{matrix}\right\|$$

where G_b, G_P, G_c are used for $1/R_b$, $1/R_P$, $1/R_c$ respectively.

$$V_{be}'=\frac{(g_{bc}-G_P)I_{cT}'-(g_{cc}+G_c+G_P)I_{bT}'}{(g_{bb}+G_b+G_P)(g_{cc}+G_c+G_P)-(g_{bc}-G_P)(g_{cb}-G_P)}$$

$$V_{ce}'=\frac{(g_{cb}-G_P)I_{bT}'-(g_{bb}+G_b+G_P)I_{cT}'}{(g_{bb}+G_b+G_P)(g_{cc}+G_c+G_P)-(g_{bc}-G_P)(g_{cb}-G_P)} \tag{26}$$

In the current literature equations 26 are approximated, usually with the expressions

$$V_{be}'\cong 0$$

$$V_{ce}'\cong\frac{-I_{coe}'}{g_{ce}^{\circ}+\alpha_{cb}G_P+G_c+G_P} \tag{27}$$

obtained with the assumptions and procedure outlined before. Again it may be pointed out that, due to the approximations involved, equations 27 do not represent a unique solution, since from equations 26 with the same assumptions one obtains

$$V_{ce}'=\frac{-I_{coe}'}{g_{cc}^{\circ}+\alpha_{cb}g_{bc}+G_c+G_P-\frac{(g_{bc}-G_P)(g_{cb}-G_P)}{g_{bb}+G_b+G_P}} \tag{28}$$

For example, with the data of equations 17 and 18 with $R_b=\infty$, $R_P=60k\Omega$, $R_c=5{,}000\Omega$, one finds from equations 26

$V_{be}'\cong 2.38$ mv per K

$V_{ce}'\cong 46.5$ mv per K

On the other hand equations 27 and 28 both provide approximately

$V_{ce}'\cong 10.5$ mv per K

From the previous discussion it appears that in general I_{bT}', V_{be}', and $\partial g_{cc}^{\circ}/\partial T\,(V_{ce}-V_{ce}^{\circ})$ are not negligible, and that the error of equations 24 and 27 is not on the safe side.

An example of temperature variable d-c network is shown in Fig. 6 for a common emitter class-*A* amplifier. In this case, if G_T is the conductance of the thermistor (at temperature *T*) and G_1 that of its shunt, equations 19 and 20 reduce respectively to

$$\begin{aligned} -I_b &=(G_T+G_1+G_2)V_{be}-G_2E_{cc} \\ V_{ce}&=E_{cc}\end{aligned} \tag{19A}$$

$$\begin{aligned} -I_b' &=(G_T+G_1+G_2)V_{be}'+G_T'V_{be} \\ V_{ce}'&=0\end{aligned} \tag{20A}$$

Therefore, from equations 20(A) and 10 one has

$$V_{be}'=\frac{-I_{bT}'-G_T'V_{be}}{g_{bb}+G_T+G_1+G_2} \tag{29}$$

$$I_c'=I_{cT}'+g_{cb}V_{be}' \tag{30}$$

As an example, consider again the transistor data, equations 17 and 18, and assume that the circuit of Fig. 6 must be designed for $I_c'=0$. A thermistor, which presents a conductance $G_T=2.7\times10^{-4}$ mhos (3,700Ω) at room temperature under an applied difference of potential $=0.2$ volt, is available. Its *B* constant is 3,500 K, its G_T' is $\sim1.05\times10^{-6}$ mhos per K. From equations 29 and 30 follows

$$I_{cT}'(g_{bb}+G_T+G_1+G_2)=g_{cb}(I_{bT}'+G_T'V_{be}) \tag{31}$$

On the other hand, substituting in equation 31, the relation

$$G_T+G_1+G_2=\frac{G_2E_{cc}-I_b}{V_{be}}$$

obtained from equation 19(A) gives the equation

$$G_2=\left(g_{cb}\frac{I_{bT}'+G_T'V_{be}}{I_{cT}'}-g_{bb}\right)\frac{V_{be}}{E_{cc}}+\frac{I_b}{E_{cc}} \tag{32}$$

With the values of the example considered it is found that $G_2=22.4\times10^{-6}$ mhos (44,700Ω) and $G_1=78\times10^{-6}$ mhos (12,800Ω).

In Fig. 7 the results of the experimental verification are shown. Having taken as reference the values at 25 C (degrees centigrade), the collector current is compensated in a temperature range extending on both sides of 25 C. It is seen that in the 25 to 50 interval I_c remains constant within 2 per cent. Compensation up to higher temperatures could be obtained taking as reference design temperature a value higher than 25 C.

If the transistor amplifier of Fig. 6 operates in class *B* (e.g., it is one half of a class-*B* push-pull amplifier), the previous analysis still holds, provided g_{bb} and g_{cb} are replaced with the appropriate values at the point of operation.

Finally it should be noticed that equation 32 provides a lower limit value for G_T.

Appendix. Recapitulation of Design Formulas

Let

$$I_{bT}'\cong\frac{\partial g_{bb}}{\partial T}(V_{be}-V_{be}^{\circ})-g_{bb}\frac{\partial V_{be}^{\circ}}{\partial T}\quad(\cong-2\times10^{-3}g_{bb}\ A\text{ per }K)$$

$$\begin{aligned} I_{cT}'&\cong\frac{\partial I_{coe}}{\partial T}+\frac{\partial\alpha_{cb}}{\partial T}+\frac{\partial g_{cc}^{\circ}}{\partial T}\times(V_{ce}-V_{ce}^{\circ})+\alpha_{cb}I_{bT}' \\ &\cong 0.1[I_{coe}+g_{cc}^{\circ}(V_{ce}-V_{ce}^{\circ})]+\alpha_{cb}I_{bT}'\end{aligned}$$

$$\Delta_g=(g_{bb}+g_{11})(g_{cc}+g_{22})-(g_{bc}+g_{12})(g_{cb}+g_{21})$$

where g_{bc} may be neglected in general.

The fundamental design equations for the temperature stabilization of a common emitter transistor amplifier are

$$V_{be}'\cong\frac{1}{\Delta_g}[(g_{bc}+g_{12})(I_{cT}'+\theta_2)-(g_{cc}+g_{22})\times (I_{bT}'+\theta_1)]$$

$$V_{ce}'\cong\frac{1}{\Delta_g}[(g_{cb}+g_{21})(I_{bT}'+\theta_1)-(g_{bb}+g_{11})\times (I_{cT}'+\theta_2)]$$

$$I_b'\cong I_{bT}'+g_{bb}V_{be}'+g_{bc}V_{ce}'=$$

$$\cong I_{bT}'+\frac{g_{bb}}{\Delta_g}[g_{12}(I_{cT}'+\theta_2)-(g_{cc}+g_{22})(I_{bT}'+\theta_1)]$$

$$I_c' \cong I_{cT}'+g_{cb}V_{be}'+g_{cc}V_{ce}'=$$

$$\cong\frac{1}{\Delta_g}\{[g_{cb}(g_{bc}+g_{12})-g_{cc}(g_{bb}+g_{11})]\times (I_{cT}'+\theta_2)+[g_{cc}(g_{cb}+g_{21})-g_{cb}\times (g_{cc}+g_{22})](I_{bT}'+\theta_1)\}+I_{cT}'$$

In the case of temperature invariant d-c bias networks, $\theta_1=\theta_2=0$. Correspondingly, the equation for I_c' may be simplified as follows:

$$I_c'\cong\frac{1}{\Delta_g}\{[g_{22}(g_{bb}+g_{11})-g_{21}(g_{bc}+g_{12})]I_{cT}'+(g_{cc}g_{21}-g_{cb}g_{22})I_{bT}'\}$$

Finally, in the case of temperature dependent d-c bias networks, if in particular V_{ce}=constant, i.e., $V_{ce}'=0$, the design equations are simplified as follows:

$$V_{be}'\cong\frac{-(I_{bT}'+\theta_1)}{g_{bb}+g_{11}}$$

$$V_{ce}'=0$$

$$I_b' \cong\frac{g_{11}I_{bT}'-g_{bb}\theta_1}{g_{bb}+g_{11}}$$

$$I_c' \cong I_{cT}'-\frac{g_{cb}}{g_{bb}+g_{11}}(I_{bT}'+\theta_1)$$

Magnetic Frequency Multipliers and Their Rating

Part I—Frequency Triplers

WILLIAM McMURRAY
ASSOCIATE MEMBER AIEE

THERE ARE a growing number of applications in which a source of power at a higher frequency than the standard 60 or 400 cps (cycles per second) is either necessary or desirable. Rotating machines, electronic generators, and magnetic frequency multipliers are some of the devices which may be employed to obtain such a power supply. Magnetic frequency multipliers have certain inherent advantages which are leading to an expansion of their use. In this respect they are quite similar to magnetic amplifiers. Both devices consist of rugged, static components which have a high degree of reliability with a long life and which require little or no maintenance. They are available for use immediately after power is applied. They can be designed to meet the requirements of military specifications for operation under vibration, high shock, and extremes in ambient temperature. The major undesirable features of magnetic frequency multipliers are the low-input power factor and the relatively large size of the equipment. With the development of better core materials and circuits, a considerable improvement in these features has recently been achieved. Power at frequencies of two, three, four, five, or six times the input frequency may be generated with reasonable efficiency.

In any particular application, the use of a magnetic frequency multiplier is determined by the relative importance of its advantages and disadvantages in that application. Factors which must be considered are system performance, size, cost, efficiency, reliability, and maintenance required. Where a high-frequency power supply is necessary to obtain satisfactory performance of a system, the static frequency multiplier should be compared with other types of frequency converters of the same rating. In other applications, a high-frequency source may be a desirable alternative to the available power supply. Here the relative merit of the over-all system with and without a frequency converter should be considered.

The object of this paper is to present a method, with examples, for analyzing the performance and size of magnetic frequency multipliers. Part I deals with frequency triplers; Part II, dealing with frequency sextuplers, is planned for future presentation.

Nomenclature

e = voltage, instantaneous, volts
E = voltage, rms value, volts
E_m = maximum value of line-to-neutral voltage, volts (base of per-unit voltage)
f = frequency of a-c supply, cps
F = rating factor of a reactor
H = magnetomotive force, oersteds
i = current, instantaneous, amperes
I = current rms value, amperes
I_d = d-c bias, amperes (base of per-unit current)
N = number of turns in a reactor winding
pf = power factor
P = power, watts
R = load resistance, ohms
t = time, seconds
ϕ = magnetic flux, instantaneous, maxwells
Φ_s = magnetic flux at saturation, maxwells (base of per-unit flux)
$\omega=2\pi f$

Subscripts

a = average value
A,B,C = phases of 3-phase supply
c = choke
i = input winding
l = load
m = maximum value of a sinusoidal wave
N = star point
$n=2,3,4,5,\ldots$ = order number of harmonic
O = system neutral
o = output winding
p = peak value of a nonsinusoidal wave

In Figs. 3, 4, and 7 through 11, showing ideal voltage, flux, and current wave forms, the scales are marked in per-unit quantities, and unity turns ratio on all reactors has been assumed.

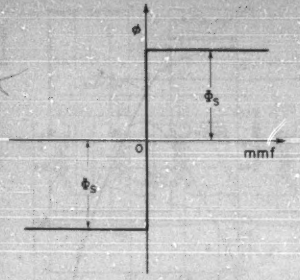

Fig. 1. Flux-magnetomotive force characteristic for ideal magnetic core material

Rating of Magnetic Frequency Multipliers

To estimate the size and cost of a magnetic frequency multiplier, it is necessary to know the volt-ampere ratings of the individual saturable reactors used in the circuit. Since these reactors are transformerlike devices, the expression of their rating in terms of an equivalent transformer rating is desirable, as it enables engineers familiar with transformer design and application to visualize readily the size of equipment required in a frequency multiplier. A similar method has been employed for many years in estimating the size of transformers for rectifiers.[1]

For a reactor used in a frequency multiplier, a rating factor F may be defined as the kva rating at the input frequency of a single-phase 2-winding transformer using an equivalent quantity of material, per kilovolt-ampere output of the frequency multiplier. Since both windings of the transformer would carry its kilovolt-ampere rating, the rating factor is calculated from the following expression, assuming resistive load

$$F=\frac{1}{2}\,\frac{\text{sum of volt-amperes of all windings}}{\text{maximum power output of complete circuit with resistive load}}$$

This factor will depend somewhat upon whether or not the multiplier output is filtered. The total rating factor of a frequency multiplier (i.e., the sum of the

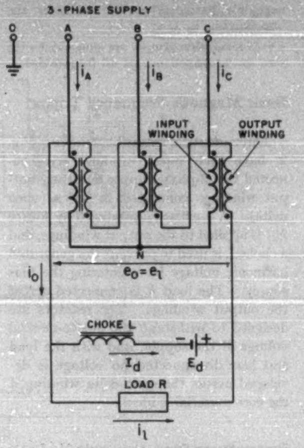

Fig. 2. Circuit diagram of basic magnetic frequency tripler

rating factors of the component reactors) is the total equivalent transformer kilovolt-ampere at supply frequency required to produce 1 kva of harmonic power.

Values of the rating factor are derived in this paper for two frequency tripler circuits employing d-c biased core reactors, as described qualitatively in reference 2. Such circuits have the advantage over circuits relying on a-c saturation[3,4] or ferroresonance[5] of being able to operate over a wide range of supply voltage and frequency variation, with only a directly proportional variation in output voltage and no change in wave shape. Furthermore, the output voltage and its wave shape do not change with load, apart from the internal impedance drop.

Also to be considered in determining the over-all size and cost of frequency multipliers are the size and cost of the d-c bias supply (usually a transformer and metallic rectifier), the bias circuit choke, the output transformer (if any), and the filter where used. The choke is about the same size as one of the multiplier reactors. The bias transformer is of much smaller rating. However, for units of low output rating these accessories form a substantial portion of the total cost.

Several differences between frequency multiplier reactors and ordinary transformers should be noted. The former are subjected to saturation and more rapid flux reversals, so that thinner core laminations may be required to reduce the eddy current loss. Also, rectangular loop core material is highly desirable. Hence the cores for frequency multipliers tend to be more expensive than transformer cores. However, to take advantage of the maximum difference between the unsaturated and saturated slopes of the magnetization curve, the cores may be designed for a greater flux swing than are transformer cores normally. Careful attention should be given during design to minimize leakage and after-saturation inductance. Furthermore, since there is relatively little

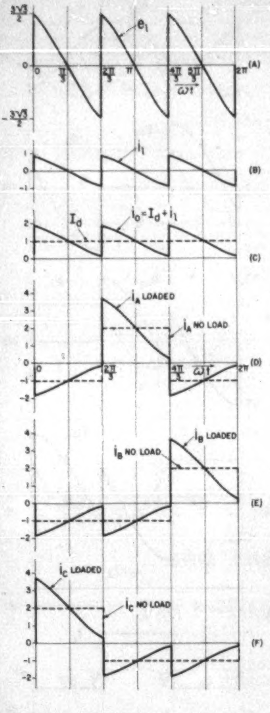

Fig. 4. Wave forms in basic frequency tripler with load

change in winding currents from no load to maximum load, less advantage may be taken of any short duty-cycle specifications, unless provision is made to vary the d-c bias as the load changes.

ASSUMPTIONS MADE IN ANALYSIS

In deriving the mode of operation of the magnetic frequency multiplier circuits and calculating the voltages and currents produced, the following assumptions are made to simplify the analysis.

1. The magnetic core material has a flux-magnetomotive-force relationship similar to that shown in Fig. 1. When the core is unsaturated, the net magnetomotive force acting upon it is negligible. After saturation, zero effective impedance is presented to currents flowing in the windings. Hysteresis and eddy currents losses are neglected.

2. Winding resistance and leakage inductance are neglected.

3. The auxiliary chokes have very large inductance and do not saturate, allowing negligible harmonic current to enter the bias supply.

4. The supply voltages are sinusoidal with zero source impedance at all frequencies.

Basic Magnetic Frequency Tripler

Three identical saturable reactors, Fig. 2, have their input windings wye-connected to a 3-phase supply and their output windings connected in series (open delta). A d-c bias I_d, produced by source E_d, is applied to the output windings, and a choke L is used to prevent the generated harmonic voltage from entering the bias supply. The load R is connected across the output windings. The reactors are designed to withstand the line-to-neutral voltage of the supply, and with the load and bias disconnected no voltage is developed across the open-delta winding if the core material is ideal.

STEADY-STATE OPERATION WITH NO LOAD

With direct current flowing in the output windings in a direction to bias the cores with conventionally positive polarity, Fig. 2, the wave forms of Fig. 3 are generated when steady-state conditions have been reached, as may be deduced from the following considerations.

At any given instant, at least one of the 3-phase input currents will flow toward the star point N of the input windings, aiding the magnetomotive force of the bias current. Therefore at least one reactor is saturated and unable to withstand voltage. However, at least two reactors must be unsaturated to withstand the 3-phase supply voltages. Hence at any time, one and only one of the reactors is saturated. Since the circuit is symmetrical with respect to the three phases, each reactor is saturated for one-third of every cycle. Also, the voltages existing between any two points of the input circuit can contain only alternating components. These conditions are satisfied only for the mode of operation illustrated in Fig. 3, in which saturation occurs from $2\pi/3$ to $4\pi/3$ radians of each phase voltage cycle. N follows the voltage of the line to which the instantaneously saturated reactor is connected. Hence the voltage e_{ON} between the system neutral O and N has the triple-frequency saw-toothed wave form of Fig. 3(A).

The individual reactor voltages and fluxes, Fig. 3(B), (C), and (D) are

$$e_{NA} = e_{OA} - e_{ON} \qquad (1)$$

$$e_{NB} = e_{OB} - e_{ON} \qquad (2)$$

$$e_{NC} = e_{OC} - e_{ON} \qquad (3)$$

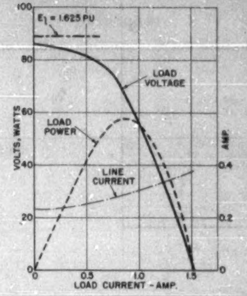

Fig. 5. Performance characteristics of basic frequency tripler

$$\phi_A = \frac{10^8}{N_i} \int e_{NA}\, dt \qquad (4)$$

The two reactors which are unsaturated at a given instant have zero net ampere-turns acting upon them; see Fig. 1. Hence a current equal to the bias current times N_i/N_o must flow out of each of their input windings, and a current of twice this value must flow into the third reactor, which is saturated. The total magnetomotive force, acting to saturate the third reactor, is therefore three times the bias ampere-turns. The input currents have the asymmetrical wave shapes of Fig. 3(F), (G), and (H).

The load voltage e_l, Fig. 4(A), is the sum of the voltages induced in the three series output windings e_o

$$e_l = e_O = -\frac{N_o}{N_i}(e_{NA} + e_{NB} + e_{NC})$$
$$= \frac{N_o}{N_i}(-e_{OA} + e_{ON} - e_{OB} + e_{ON} - e_{OC} + e_{ON}) \qquad (5)$$
$$= \frac{N_o}{N_i} 3e_{ON}$$

By Fourier analysis, this voltage may be expressed by the series

$$e_l = \frac{N_o}{N_i} E_m \frac{9\sqrt{3}}{\pi} \sum_{n=1}^{\infty} \frac{3_n}{(3n)^2 - 1} \sin 3n\omega t$$
$$= \frac{N_o}{N_i} E_m (1.861 \sin 3\omega t + 0.851 \sin 6\omega t \qquad (6)$$
$$+ 0.558 \sin 9\,\omega t + 0.416 \sin 12\omega t \ldots)$$

LOAD CONDITION

When the output windings are resistively loaded, a load current i_l of the same wave shape as the load voltage flows, Fig. 4(B), and is superposed upon the bias current in the output windings, Fig. 4(C). It is reflected into the input

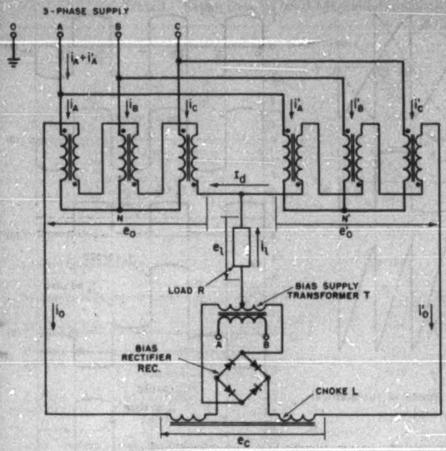

Fig. 6. Circuit diagram of symmetrical magnetic frequency tripler

currents as shown in Fig. 4(D), (E), (F). As the load resistance is decreased, a point will be reached at which the peak value of the load current equals the bias current. The corresponding value of the load resistance may be defined as the critical load resistance. For lower values of load resistance, the mode of operation of the circuit changes and the load voltage drops rapidly; see Fig. 5. This mode is not of practical interest and will not be discussed further. A detailed analysis is given in reference 6.

CALCULATION OF PERFORMANCE AND RATING OF BASIC FREQUENCY TRIPLER

The calculation of the performance of this circuit will be described in some detail, to illustrate the method which may be applied to most frequency multipliers using biased-core reactors. Unity turns ratio is assumed, to simplify the equations.

The load voltage, Fig. 4(A), is characterized by

peak value

$$E_{lP}=\frac{3\sqrt{3}}{2}E_m=2.598E_m \tag{7}$$

average value

$$E_{la}=\frac{3}{\pi}\int_0^{\frac{\pi}{3}}3E_m\sin\theta d\theta=\frac{9}{2\pi}E_m=1.432E_m \tag{8}$$

effective value

$$E_l=\sqrt{\frac{3}{\pi}\int_0^{\frac{\pi}{3}}(3E_m\sin\theta)^2d\theta}$$

$$=\frac{3}{\sqrt{2}}\sqrt{1-\frac{3\sqrt{3}}{4\pi}}E_m=1.625E_m \tag{9}$$

The voltage rating of each of the reactor windings at the input frequency is equal to the line-to-neutral voltage of the supply

$$E=\frac{E_m}{\sqrt{2}}=0.707\ E_m \tag{10}$$

For maximum power output into the load, the peak value of the load current I_{lp} is equal to the d-c bias I_d, and the critical load resistance is

$$R=\frac{E_{lp}}{I_d}=2.598\frac{E_m}{I_d} \tag{11}$$

Then the average and effective values of the maximum load current are

$$I_{la}=\frac{1.432}{2.598}I_d=0.511\ I_d \tag{12}$$

$$I_l=\frac{1.625}{2.598}I_d=0.625\ I_d \tag{13}$$

The maximum load power is therefore

$$P_{lp}=E_lI_l=1.625E_m\times0.625\ I_d$$
$$=1.016\ E_mI_d \tag{14}$$

At no load, the current in the output winding is the d-c bias alone

$$I_o=I_d \tag{15}$$

and the effective value of the current in the input winding is

$$I_i=\sqrt{\frac{2\ I_o^2+(2I_o)^2}{3}}=\sqrt{2}I_o \tag{16}$$
$$=1.414\ I_d$$

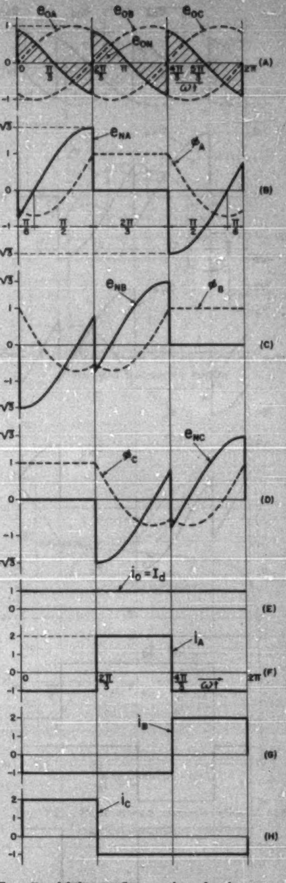

Fig. 7. Voltage, flux, and no-load current wave forms in first section of symmetrical frequency tripler

At maximum load, effective value of the current in the output winding is

$$I_o=\sqrt{I_d^2+(0.625\ I_d)^2}=1.179\ I_d \tag{17}$$

and the effective value of the current in the input winding is

$$I_i=\sqrt{2}I_o=1.667\ I_d \tag{18}$$

Thus the rating factor of one reactor is

$$F=\frac{0.707E_m(1.179I_d+1.667\ I_d)}{2\times1.016\ E_mI_d} \tag{19}$$
$$=0.990$$

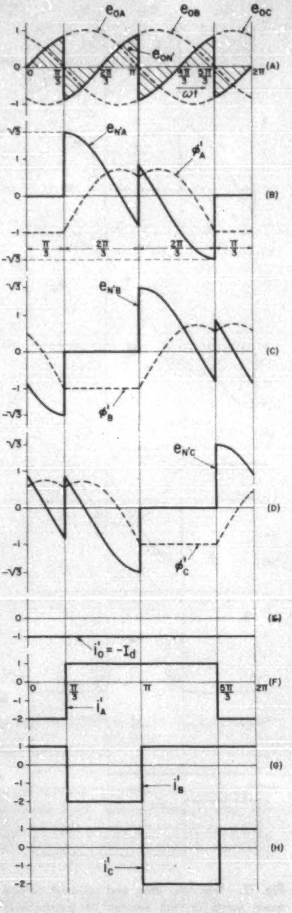

Fig. 8. Voltage, flux, and no-load current wave forms in second section of symmetrical frequency tripler

The total rating factor of the basic frequency tripler circuit is three times the value of equation 19

$$\sum F = 3F = 2.970 \tag{20}$$

Defining the effective power factor of the circuit as

$$\text{pf} = \frac{\text{power output into load}}{3 \times \text{rms phase voltage} \times \text{rms line current}} \tag{21}$$

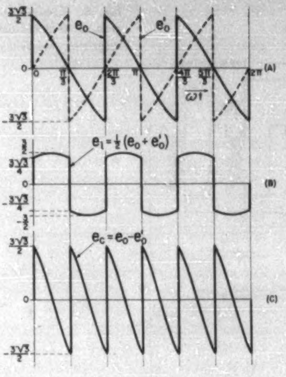

Fig. 9. Voltage wave forms in symmetrical frequency tripler

the maximum value for the power factor of the basic tripler is

$$\text{pf} = \frac{1.016\ E_m I_d}{3 \times 0.707\ E_m \times 1.667\ I_d} = 0.287 \tag{22}$$

These results have been summarized in Table I.

If an ideal filter were connected in series with the load, so that a pure third harmonic current is drawn, the calculations should be modified. The peak value of the load current, corresponding to maximum load power, is still equal to the d-c bias

$$I_{lm3} = I_d \tag{23}$$

The maximum third harmonic load power is therefore

$$P_{lm3} = \frac{1}{2} E_{lm3} \times I_{lm3} \tag{24}$$

$$= \frac{1}{2} \times 1.861 E_m \times I_d = 0.930 E_m I_d$$

At maximum load, the effective value of the current in the output winding is

$$I_o = \sqrt{I_d^2 + \frac{1}{2} I_d^2} = \sqrt{\frac{3}{2}} I_d = 1.225 I_d \tag{25}$$

The effective value of the current in the input winding is

$$I_1 = \sqrt{2} I_o = \sqrt{3} I_d = 1.732 I_d \tag{26}$$

Hence the rating factor of one reactor is

$$F = \frac{0.707\ E_m (1.225\ I_d + 1.732\ I_d)}{2 \times 0.930\ E_m I_d} = 1.124 \tag{27}$$

The total rating factor of the basic

Table I. Rating Data for Ideal Magnetic Frequency Triplers

		Basic Tripler		Symmetrical Tripler	
Load voltage	peak value	$\frac{3\sqrt{3}}{2}$	2.598	$\frac{3}{2}$	1.5
	average value	$\frac{9}{2\pi}$	1.432	$\frac{9}{2\pi}$	1.432
	effective rms value	$\frac{3}{\sqrt{2}}\sqrt{1-\frac{3\sqrt{3}}{4\pi}}$	1.625	$\frac{3}{2\sqrt{2}}\sqrt{1+\frac{3\sqrt{3}}{2\pi}}$	1.434
	maximum value of fundamental component	$\frac{27\sqrt{3}}{8\pi}$	1.861	$\frac{27\sqrt{3}}{8\pi}$	1.861
Voltage rating of reactor		$\frac{1}{\sqrt{2}}$	0.707	$\frac{1}{\sqrt{2}}$	0.707
Critical load resistance		$\frac{3\sqrt{3}}{2}$	2.598	$\frac{3}{4}$	0.75
Maximum load current, rms value		$\sqrt{\frac{2}{3}}\sqrt{1-\frac{3\sqrt{3}}{4\pi}}$	0.625	$\sqrt{2}\sqrt{1+\frac{3\sqrt{3}}{2\pi}}$	1.912
Maximum load power		$\sqrt{3}\left(1-\frac{3\sqrt{3}}{4\pi}\right)$	1.016	$\frac{3}{2}\left(1+\frac{3\sqrt{3}}{2\pi}\right)$	2.755
Current in output winding, rms value	no load	1	1.000	1	1.000
	maximum load	$\sqrt{\frac{5}{3}-\frac{\sqrt{3}}{2\pi}}$	1.179	$\sqrt{\frac{3}{2}}\sqrt{1+\frac{\sqrt{3}}{2\pi}}$	1.383
Current in input winding, rms value	no load	$\sqrt{2}$	1.414	$\sqrt{2}$	1.414
	maximum load	$\sqrt{2}\sqrt{\frac{5}{3}-\frac{\sqrt{3}}{2\pi}}$	1.667	$\sqrt{3}\sqrt{1+\frac{\sqrt{3}}{2\pi}}$	1.956
Line current, rms value	no load	$\sqrt{2}$	1.414	$\sqrt{6}$	2.449
	maximum load	$\sqrt{2}\sqrt{\frac{5}{3}-\frac{\sqrt{3}}{2\pi}}$	1.667	$\sqrt{7+\frac{3\sqrt{3}}{2\pi}}$	2.798
Rating factor of one reactor		$\frac{(1+\sqrt{2})\sqrt{\frac{5}{3}-\frac{\sqrt{3}}{2\pi}}}{2\sqrt{6}\left(1-\frac{3\sqrt{3}}{4\pi}\right)}$	0.990	$\frac{(1+\sqrt{3})\sqrt{1+\frac{\sqrt{3}}{2\pi}}}{2\sqrt{3}\left(1+\frac{3\sqrt{3}}{2\pi}\right)}$	0.420
Total rating factor of circuit			2.970		2.572
Effective power factor of circuit			0.287		0.464

All values are per unit for unity turns ratio on the reactors. Bases of per-unit quantities:
Voltage = E_m, maximum value of line-to-neutral voltage, volts
Current = I_d, direct current bias, amperes
Resistance = E_m/I_d
Power = E_mI_d

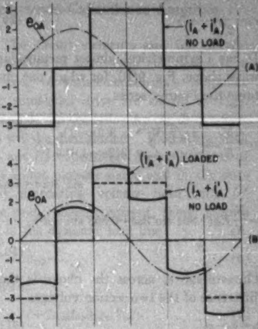

Fig. 11. Wave forms of line current in symmetrical frequency tripler

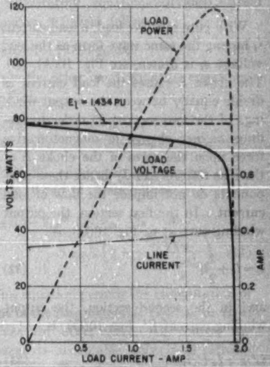

Fig. 12. Performance characteristics of symmetrical frequency tripler

frequency tripler with filtered output is three times the value of equation 27

$$\sum F=3F=3.372 \tag{28}$$

By way of comparison, the total rating factor of a similar type of frequency doubler with filtered output is approximately 2; see reference 2, equation 12.

PERFORMANCE DATA

Performance characteristics of an experimental basic frequency tripler are shown in Fig. 5, which has been obtained from reference 6, and may be considered typical for this circuit. The saturable reactor specifications are as follows:

Core: Arnold Engineering Company toroidal tape-wound core, Catalogue no. 5468-D2, 0.002-inch Deltamax tape (grain-oriented 50 per cent nickel, 50 per cent iron alloy), inside diameter 2.5 inches, outside diameter 3.5 inches, height 1.0 inch.

Windings: Input winding 2,550 turns 0.0201-inch wire, output winding 380 turns 0.0508-inch wire, bias winding 152 turns 0.0359-inch wire.

Supply: 450 volts, 3-phase, 60 cps, bias current 2.5 amperes

Note that a separate bias winding was used. In the experimental circuit, the choke was considerably larger than would normally be used.

Symmetrical Magnetic Frequency Tripler

This circuit, Fig. 6, has two sections, each consisting of a group of saturable reactors of the same type used in the basic frequency tripler. The output windings of the two sections are connected in series opposition, and carry a d-c I_d which biases the two groups of reactors with opposite polarity. The method of biasing shown in Fig. 6, consisting of the bias supply transformer T and bias rectifier *REC*, has been found convenient in practice. No direct current will flow through the load R if the sections are perfectly balanced. The choke L has two equal windings which are closely coupled.

STEADY-STATE OPERATION WITH NO LOAD

The first section of the circuit, in which the reactors are biased with conventionally positive polarity, develops the wave forms of Fig. 7 under no-load conditions. These wave forms are identical with those of Fig. 3 for the basic frequency tripler with positive bias. The reactors in the second section of the circuit are biased with conventionally negative polarity, and they generate wave forms as shown in Fig. 8, which are phase-shifted by π radians and reversed in polarity with respect to the wave forms produced by the first section.

The voltages e_o and e_o' developed in the output windings of the two sections are shown in Fig. 9(A). By the action of the choke L, the voltage e_l appearing across the load R is the instantaneous average of the voltages e_o and e_o'

$$e_l=\frac{1}{2}(e_o+e_o') \tag{29}$$

It has a symmetrical, almost rectangular wave shape, Fig. 9(B), for which one obtains the Fourier series

$$e_l=\frac{N_o}{N_i}E_m\frac{9\sqrt{3}}{\pi}\sum_{n=1}^{\infty}\frac{3(2n-1)}{[3(2n-1)]^2-1}\times \sin 3(2n-1)\omega t$$

$$=\frac{N_o}{N_i}E_m(1.861 \sin 3\omega t+0.558 \sin 9\omega t+\ldots) \tag{30}$$

The voltage e_c across the choke is the difference of the two section voltages

$$e_c=e_o-e_o' \tag{31}$$

This voltage e_c contains no harmonics of lower order than the sixth, and has a saw-toothed wave shape; see Fig. 9(C).

LOAD CONDITION

With pure resistive load, a load current i_l having the same wave form as the load voltage e_l is drawn, see Fig. 10(A), (B). The choke L causes the load current to divide equally between the output windings of the two sections in order to produce no net change in magnetomotive force upon the cores of the choke L or the bias transformer T; hence these components do not impede the flow of load current. In the first section, the output winding current i_o, Fig. 10(C), is

$$i_o=I_d+\frac{1}{2}i_l \tag{32}$$

and in the second section, the output winding current i_o', Fig. 10(G), is

$$i_o'=-I_d+\frac{1}{2}i_l \tag{33}$$

These currents are reflected into the input windings of the six reactors as illustrated in Fig. 10(D), (E), (F), and Fig. 10(H), (I), (J), respectively. The total current drawn from phase A of the supply, Fig. 11, is the sum of the currents drawn by phase A of each section; the currents in phases B and C are similar. It is seen that the line currents possess half-wave symmetry.

Maximum power output into the load is obtained when the peak value of the load current equals twice the direct bias current, corresponding to a critical value of load resistance. When the load resistance is smaller than the critical value, a change in the mode of operation occurs and the load voltage drops abruptly; see Fig. 12. The circuit is effectively a source of constant triple-frequency current with rectangular wave shape of magnitude $2\times I_d$ when the load impedance is small.

PERFORMANCE DATA

The rating of the symmetrical frequency tripler may be calculated by the same method as already applied to the basic frequency tripler. Data for the case of unfiltered output into resistive load are given in Table I. Performance characteristics of a typical circuit[5] are shown in Fig. 12. The saturable reactors are the same as were used in the basic frequency tripler experimental unit. It is observed that the symmetrical tripler is superior to the basic tripler in performance, output wave form and rating factor. However, the basic tripler is economical in the smaller sizes.

Discussion

With sharply saturating core material the actual wave shapes produced in a frequency multiplier circuit are very close to the ideal derived by means of the simplified analysis. For design purposes the actual voltages and currents in a circuit may be predicted with normally sufficient accuracy from the ideal by application of empirical "loss" factors, depending upon the core material, if its characteristic does not differ greatly from Fig. 1.

Magnetic frequency multipliers tend to have relatively high regulation, due to leakage inductance and the after-saturation inductance of the nonideal reactors, which may be minimized by careful design. A series capacitor may be used to resonate with the effective inductance of the unit, improving regulation. In some applications, a tuned filter may be used to eliminate undesirable harmonics. This modifies the currents in the circuit under loaded conditions and changes the rating factor somewhat, as shown in the case of the basic tripler.

There are various possible modifications of the circuit arrangements described, which do not change the fundamental mode of operation. For example, separate output and bias windings may be provided, as in the case of the experimental units, to isolate the d-c bias supply from the load. The rating factors of such arrangements will, in general, differ from the values derived here. In addition, a number of constructional variations are possible, such as making the output winding common to several cores, like an amplistat control winding.

Optimum Design of Common-Emitter Transistor Audio Amplifiers

L. M. VALLESE
ASSOCIATE MEMBER AIEE

Synopsis: An analytical procedure of design of common-emitter transistor audio amplifiers is given. The conditions of optimum design for maximum power output are derived for resistance-capacitance and transformer-coupled amplifiers, taking in consideration the limitations of the collector characteristics. Finally, the distortion caused by nonlinearity of the collector characteristic is computed.

THE problem of the design of amplifiers for maximum power output is of great importance for transistors. Differently from vacuum-tube amplifiers which have theoretically infinite power gain but finite power output, transistor amplifiers have finite power gain and finite power output. For this reason it is often important to maximize them for power output at least in the last two stages. Such design is obtained with consideration of the maximum limitations of the collector electric characteristics; in particular it is required to determine the quiescent point of operation so that maximum possible input drive may be obtained with the available linear range and the required stabilization of the operating point. At present the analysis of these conditions is performed graphically, following a cut-and-trial procedure which requires specialized skill.[1,2]

In the following an analytical procedure of design, based on a linear approximation of the characteristics, will be given. Its aim is to provide a systematic approach and to emphasize the interdependence of the variables involved and the degrees of freedom available to the designer. A similar procedure could be developed for pentode amplifiers, the design of which is generally obtained graphically. It will be assumed that the short-circuit current gain α_{cb} is independent of the emitter current. Only the common-emitter configuration will be considered in detail in this paper, since the same procedure applies to the other configurations. The problem of temperature stabilization will not be considered and it will be assumed that the transistor characteristics are given in condition of temperature steady state. In practice it will be necessary to apportion a suitable part of the linear region for thermal variations.

In Fig. 1 a typical example of input and output characteristics of common-emitter low-power p-n-p transistor is shown. For linear amplification, these characteristics should consist of parallel straight lines; in the following it will be assumed that within certain ranges such is the case. In a later section the problem of the distortion will be discussed.

The linearized input and output characteristics may be represented with the equations

$$I_b=g_{bb}(V_{be}-V_{be}^0)+g_{bc}V_{ce} \tag{1}$$

if

$$|I_b|\geq|I_{b\,\min}|$$

$$|V_{be}\geq|V_{be\,\min}|$$

and

$$I_c=I_0'+\alpha_{cb}(I_b-I_b')+g_{ce}V_{ce} \tag{2}$$

if $|I_b|\geq|I_b'|\geq|{}_bI_{b\,\min}|$. The boundaries of the linear region in the collector plane are

$$|V_{ce}'|\leq|V_{ce}|\leq|V_{ce\,\max}| \tag{3}$$

$$|I_c'|\leq|I_c|\leq|I_{c\,\max}| \tag{4}$$

$$V_{ceQ}I_{cQ}\leq P_c \tag{5}$$

The explanation of the various symbols is given in Appendix I. It should be noted that, in most cases, the parameter g_{bc} is practically negligible in a considerable range of the variables. The design will be carried out only in the collector plane.

Resistance-Capacitance Amplifier

The circuit elements and the electric quantities of interest in the design of a typical resistance-capacitance amplifier for sinusoidal drive are shown in Figs. 2 and 3. In the following the drop across G_3 will be disregarded. Indicating with I_{bs} and E_0 respectively the amplitudes of the input current signal and of the output alternating voltage, and with I_c'' the peak collector current, there follows from the dynamic load line

$$I_c''=2\,I_{cQ}-I_c' \tag{6}$$

where

$$I_c''=I_0'+2\alpha_{cb}I_{bs}+g_{ce}V_{ce}' \tag{7}$$

$$I_{cQ}=(G_2+G_L)E_0+I_c' \tag{8}$$

$$I_{cQ}=G_2(E_{cc}-V_{ce}'-E_0) \tag{9}$$

$$I_c'=I_0'+g_{cc}(V_{ce}'+2E_0)$$

Substituting equations 7 and 8 in equation 6, there follows

$$\alpha_{cb}I_{bs}=(G_2+G_L+g_{ce})E_0 \tag{10}$$

On the other hand, equating equations 8 and 9

$$G_2(E_{cc}-V_{ce}')-g_{ce}V_{ce}'-I_0'=(2G_2+2g_{ce}+G_L)E_0 \tag{11}$$

Finally, eliminating E_0 between equations 10 and 11, there follows

$$G_2(E_{cc}-V_{ce}')-g_{ce}V_{ce}'-I_0'=\alpha_{cb}I_{bs}\left(1+\frac{G_2+g_{ce}}{G_2+g_{ce}+G_L}\right) \tag{12}$$

This equation permits the computation of one of the parameters G_2, G_L, E_{cc}, or I_{bs} if given the other three. Of course, the design is acceptable only if it satisfies the limitations of equations 3, 4, and 5.

The design for maximum power output generally is of academic interest because of the large d-c supply voltage required and of the low collector efficiency involved; however, it is important as a reference optimum condition. Two separate cases must be considered, i.e., the design for given I_{bs} and that for given E_{cc}; it should be noticed that the first case also corresponds to maximum power gain, since the input power is $I_{bs}^2/2G_{in}$.

When I_{bs} is given, expressing E_0 with equation 10 and maximizing the quantity $P_L = G_LE_0^2/2$, G_2 is found as small as possible and

$$G_L=G_2+g_{ce} \tag{13}$$

Correspondingly, the maximum power output and the related power gain are

$$P_{L\,\max}=\alpha_{cb}^2I_{bs}^2/8G_L$$

$$A_P=\alpha_{cb}^2G_{in}/4G_L \tag{14}$$

Paper 55-667, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the National Electronics Conference, Chicago, Ill., October 3–5, 1955, and re-presented at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted March 28, 1955; made available for printing December 2, 1955.

L. M. VALLESE is with Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

The work described has been done at the Microwave Research Institute of the Polytechnic Institute of Brooklyn, under a contract sponsored by the Office of Naval Research.

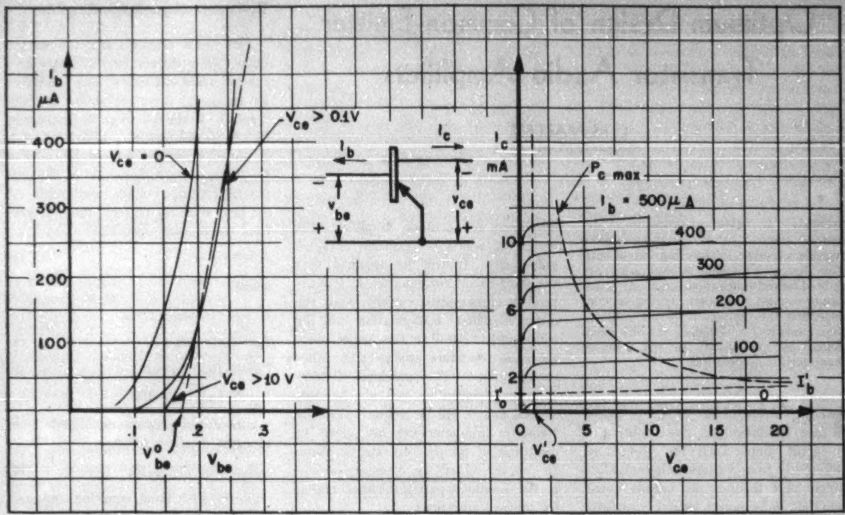

Fig. 1. Example of input and output characteristics of low-power common-emitter transistor

The lowest value of G_2 is obtained considering that the limit position of the quiescent point is at the intersection of the I_c characteristic corresponding to $I_b = I_{bQ} = I_b' + I_{bs}$ with either the P_c hyperbola or with the vertical line

$$V_{ce} = V_{ceQ} = (V_{ce\ max} + V_{ce}')/2$$

whichever is smaller.

In the first case from

$$I_{cQ} = I_0' + \alpha_{cb} I_{bs} + g_{cc} V_{ceQ} = P_c / V_{ceQ}$$

there follows

$$V_{ceQ} = -\frac{I_0' + \alpha_{cb} I_{bs}}{2 g_{cc}} + \sqrt{\frac{(I_0' + \alpha_{cb} I_{bs})^2}{4 g_{cc}^2} + \frac{P_c}{g_{cc}}} \quad (15)$$

In particular, if g_{cc} is neglected, it is found approximately in excess

$$V_{ceQ} \cong \frac{P_c}{I_0' + \alpha_{cb} I_{bs}} \quad (16)$$

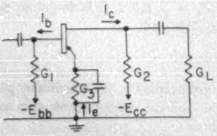

Fig. 2. Common-emitter resistance-capacitance amplifier

From the value of V_{ceQ}, $E_0 = V_{ceQ} - V_{ce}'$ is obtained, and from equation 10 is obtained

$$G_L = \frac{\alpha_{cb} I_{bs}}{2 E_0}$$

$$G_2 = G_L - g_{cc} \quad (17)$$

Upper values of P_L are $P_c/4$ or $(\alpha_{cb} I_{bs} V_{cemax})/8$ according if $I_{bs} \gtrless [(2P_c)/(\alpha_{cb} V_{cemxa})]$

Finally, E_{cc} follows from equation 12

$$E_{cc} = V_{ce}' + \frac{1}{G_2}\left(\frac{3}{2}\alpha_{cb} I_{bs} + g_{cc} V_{ce}' + I_0'\right)$$

Consider now the optimum design for given E_{cc}. Expressing E_0 from equation 11 and maximizing P_L, it is found that G_2 should be as large as possible and

$$G_L = 2(G_2 + g_{cc}) \quad (18)$$

As a first approximate uppermost value for G_2, a value of $4P_c/E_{cc}^2$ for which the static load line is tangent to the P_c hyperbola is assumed. Correspondingly, I_{bs} follows from equation 12, which with the substitution into equation 18 reads

$$I_{bs} = \frac{3}{4\alpha_{cb}} (G_2(E_{cc} - V_{ce}') - g_{cc} V_{ce}' - I_0') \quad (19)$$

These values of G_2 and I_{bs} are acceptable if

$$I_{bs} \leq (I_{c\ max} - I_0' - g_{cc} V_{ce}')/2\alpha_{cb} \quad (20)$$

If the latter condition is not satisfied, I_{bs} will be taken equal to the right-hand member of equation 20 and G_2 will follow from equation 19.

In first approximation, the design will be limited by the $I_{c\ max}$ value or by the P_c value, Fig. 4, depending on whether

$$E_{cc} > 6P_c/I_{c\ max} \text{ or } E_{cc} < \frac{6P_c}{I_{c\ max}}$$

From the values of I_{bs} and G_L there follows that $E_0 = 2\alpha_{cb} I_{bs}/3G_L$ and, correspondingly, the maximum power output and the related power gain are

$$P_{L\ max} = \frac{2\alpha_{cb}^2 I_{bs}^2}{9 G_L}$$

$$A_P = \frac{4}{9} \alpha_{cb}^2 \frac{G_{in}}{G_L}$$

Approximate upper values of $P_{L\ max}$ are $P_c/4$ for the P_c limited case and $E_{cc} I_{c\ max}/24$ for the $I_{c\ max}$ limited case.

The design of the input circuit follows simply after the design of the output circuit has been obtained. The value of E_{cc} must be adjusted to take into account the drop of G_3.

Transformer-Coupled Amplifier

The procedure of design of the transformer coupled amplifier, Fig. 5, is similar to that developed for the resistance-

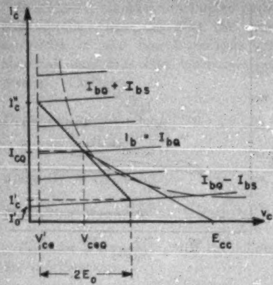

Fig. 3. Static and dynamic load lines of common-emitter resistance-capacitance amplifier

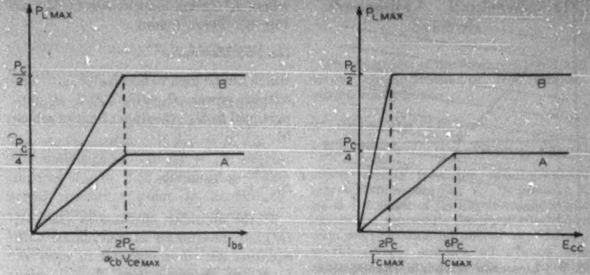

Fig. 4. Upper boundaries of $P_{L\,max}$ for given I_{bs} and for given E_{cc}

A—Resistance-capacitance amplifier
B—Transformer-coupled amplifier

capacitance amplifier, but results in simpler equations since

$$V_{ceQ} = E_{cc} = E_0 + V_{ce}'$$

Indicating with G_L', the primary transformed load admittance, there results from the dynamic load line in the collector plane

$$I_c'' = 2I_{cQ} - I_c'$$

where

$$I_c'' = I_0' + 2\alpha_{cb}I_{bs} + g_{cc}V_{ce}'$$

$$I_c' = I_0' + g_{cc}(V_{ce}' + 2E_0)$$

$$I_{cQ} = G_L'E_0 + I_0' + g_{cc}(V_{ce}' + 2E_0)$$

Substituting, it is found that

$$\alpha_{cb}I_{bs} = (G_L' + g_{cc})E_0 = (G_L' + g_{cc})(E_{cc} - V_{ce}') \tag{21}$$

Equation 21 permits the computation of one of the parameters G_L', E_{cc}, or I_{bs} if the other two are given. The resulting design is acceptable provided it satisfies the limitations of equations 3, 4, and 5.

The design for maximum power output may be considered again in two separate cases, i.e., for given I_{bs} and for given E_{cc}; in the first case, maximum power gain is also obtained.

For given I_{bs}

$$P_L = \frac{G_L'}{2}\,\frac{\alpha_{cb}^2 I_{bs}^2}{(G_L' + g_{cc})^2}$$

and maximum power output is obtained when $G_L' = g_{cc}$. However, this condition is not practical because, in general, it is violative of the limitations of equations 3 and 5 and because g_{cc} is too small. On the other hand, from equation 21 is obtained

$$G_L' = \frac{\alpha_{cb}I_{bs}}{E_{cc} - V_{ce}'} - g_{cc} \tag{22}$$

so that the lowest value of G_L' may be determined as a function of $E_{cc} = V_{ceQ}$. The latter is either the value of equation 15 or $(V_{ce\ max} + V_{ce}')/2$, whichever is smaller. In first approximation, E_{cc} is limited by the P_c value or by the $V_{ce\ max}$ value if

$$\alpha_{cb}I_{bs} \gtrless 2P_c/V_{ce\ max}$$

The power output and the related power gain are

$$P_{L\max} = \frac{1}{2}\left(\frac{\alpha_{cb}I_{bs}}{E_{cc} - V_{ce}'} - g_{cc}\right)(E_{cc} - V_{ce}')^2$$

$$A_P = \frac{2G_{in}}{I_{bs}^2}\,P_{L\ max}$$

Approximate upper values of $P_{L\max}$ are $P_c/2$, when E_{cc} is computed with equation 15, and $\alpha_{cb}I_{bs}V_{ce\ max}/4$ in the alternate case.

For given E_{cc}, the power output is

$$P_L = G_L'(E_{cc} - V_{ce}')^2/2$$

and maximum power output is obtained for G_L' as large as possible. The uppermost value of G_L' is obtained from equation 22, where I_{bs} is the smaller of

$$\frac{1}{\alpha_{cb}}\left(\frac{P_c}{E_{cc}} - I_0' - g_{cc}(E_{cc} - V_{ce}')\right)$$

or

$$\frac{1}{2\alpha_{cb}}\,(I_{c\ max} - I_0' - g_{cc}V_{ce}') \tag{23}$$

Approximate upper values of $P_{L\max}$, Fig. 4, are respectively for the first and the second case of equation 23, i.e., for $E_{cc} \gtrless [(2P_c)/(I_{c\ max})]$

$$P_c/2$$

$$E_{cc}I_{c\ max}/4$$

In completing the design, the value of E_{cc} should be adjusted to take into account the drop across G_3.

Transformer-Coupled Push-Pull Amplifier

Likewise, in the case of vacuum tubes,[3] the procedure of design of transformer-coupled push-pull amplifiers is simplified with the introduction of the composite transistor. The latter is defined as the linear equivalent transistor which has the same gain and power output as the push-pull amplifier, Fig. 6, but has an

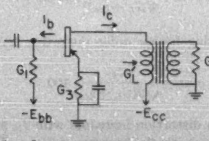

Fig. 5. Common-emitter transformer-coupled amplifier

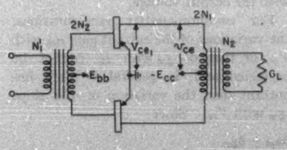

Fig. 6. Common-emitter push-pull amplifier

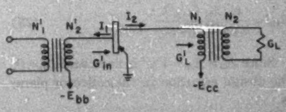

Fig. 7. Composite transistor amplifier

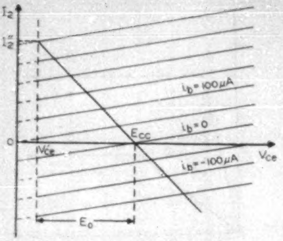

Fig. 8. Linearized composite characteristics of push-pull common-emitter amplifier

input transformer of ratio N_1' to N_2' and an output transformer of ratio N_1 to N_2, with the same source and load admittances; see Fig. 7. If the currents and voltages of the two transistors of the push-pull amplifier are indicated respectively with the subscripts 1 and 2, the corresponding currents and voltages of the composite transistor are

$$I_1 = I_{b1} - I_{b2},\ V_1 = V_{be1}$$

$$I_2 = I_{c1} - I_{c2},\ V_2 = V_{ce1}$$

Indicating with i_b, v_{be}, i_c, and v_{ce} the instantaneous values of the alternating currents and voltages

$$I_{b1} = I_{bQ} + i_b,\ I_{b2} = I_{bQ} - i_b$$

$$V_{be1} = E_{bb} + v_{be},\ V_{be2} = E_{bb} - v_{be} = 2E_{bb} - V_{be1}$$

$$V_{ce1} = E_{cc} - v_{ce},\ V_{ce2} = E_{cc} + v_{ce} = 2E_{cc} - V_{ce1}$$

The linearized composite input and output characteristics are

$$I_1 = k_{11}(V_{be1} - E_{bb}) + k_{12}v_{ce} \tag{24}$$

$$I_2 = k_{21}i_b + k_{22}(V_{ce1} - E_{cc})$$

where, for class-A operation, $k_{11} = 2g_{bb}$, $k_{12} = 2g_{bc}$, $k_{21} = 2\alpha_{cb}$, and $k_{22} = 2g_{ce}$, and for class-B operation $(AB-B)$, $k_{11} \cong g_{bb}$, $k_{12} \cong g_{bc}$, $k_{21} \cong \alpha_{cb}$, and $k_{22} \cong g_{cc}$. Equations 24 ordinarily are found by graphical construction after the quiescent point of operation of the component transistors has been determined, as shown in the previous section.

The slope of the composite load line in the collector plane is $-G_L' = -G_L(N_2/N_1)^2$, while that of the input dynamic characteristic in the base plane is

$$G_{in}' = \frac{k_{11}(k_{22} + G_L')}{k_{12}k_{21} + k_{22} + G_L'} \tag{25}$$

Since $E_0 = E_{cc} - V_{ce}'$ is fixed and $I_{2Q} = 0$, the design equation in the collector plane is

$$I_2'' = G_L'E_0 = k_{21}I_{bs} + k_{22}(V_{ce}' - E_{cc})$$

where I_2'' is the peak value of I_2; see Fig. 8. There follows

$$(k_{22} + G_L')E_0 = k_{21}I_{bs}$$

which can be used to find G_L' or I_{bs}. The output power $P_L = (G_L'E_0^2)/2$ is proportional to G_L', the upper limit of which is

$$\frac{k_{21}}{E_{cc} - V_{ce}'} I_{bs\,\max} - k_{22}$$

If the amplifier operates in class A, $I_{bs\,\max}$ is determined in accordance with equation 23; if it operates in class B, $I_{bs\,\max}$ is obtained from the following equation

$$I_{bs\,\max} = \frac{1}{\alpha_{cb}}(I_c - I_0' - g_{ce}V_{ce}')$$

where I_c is the smaller of $I_{c\,\max}$ and $P_c/(1/\pi - 1/4)E_{cc}$. Correspondingly, the approximate upper limits of the output power are, in class A, for $E_{cc} \lessgtr 2P_c/I_{c\,\max}$

$$\frac{1}{2} I_{c\,\max}E_{cc} \text{ or } P_c$$

and, in class B, for $E_{cc} \lessgtr P_c/(1/\pi - 1/4) I_{c\,\max}$

$$\frac{1}{2} I_{c\,\max}E_{cc} \qquad P_c/\left(\frac{2}{\pi} - \frac{1}{2}\right) = 7.3P_c$$

Finally, the input admittance of the primary input transformer is $(N_1'/N_2')^2 G_{in}'$, where G_{in}' is given by equation 25.

Collector Distortion

Distortion occurs in power transistor amplifiers because of nonlinearities of the input and the output characteristics. Although these are not additive, they have been investigated separately[1] in order to arrive at simple approximate expressions. The base distortion has been obtained with the assumption that the input admittance varies directly with I_e; the collector distortion (excluding the presence of undesirable clipping) has been obtained expressing I_c as a power series and assuming that the current gain is invariant with changes in operating voltage and current, and the slope of the output characteristics varies with the output voltage.

For common-emitter configurations, the variations of the current gain α_{cb} with V_{ce}, or that of g_{ce} with I_b, cannot be neglected and, in general, is more important than the variation of the slope g_{ce} with V_{ce}. Since

$$\frac{\partial \alpha_{cb}}{\partial V_{ce}} = \frac{\partial g_{ce}}{\partial I_b}$$

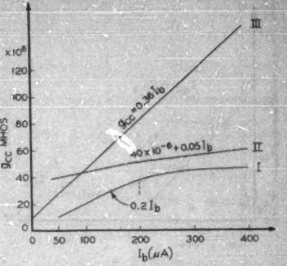

Fig. 9. Plot of g_{ce} versus I_b for three different transistors

the latter quantity may be obtained from a plot of g_{ce} versus I_b; see Fig. 9.

It is important to evaluate the collector distortion and to take into account the previous considerations. The power series expansion of I_c about the quiescent point may be written with the use of small letters for incremental variations, letting $\gamma = (\partial\alpha_{cb})/(\partial V_{ce})$ and neglecting $(\partial g_{ce})/(\partial V_{ce})$

$$i_c \cong \alpha_{cb}i_b + g_{ce}v_{ce} + \gamma v_{ce}i_b \tag{26}$$

where α_{cb}, g_{ce}, and γ are evaluated at the quiescent point.

In the case of a single transformer-coupled amplifier

$$i_c = -G_L'v_{ce}$$

and therefore

$$v_{ce} = \frac{-\alpha_{cb}i_b}{G_L' + g_{ce} + \gamma i_b}$$

Expanding in power series and assuming that $i_b = I_{bs}\cos\omega t$, there follows

$$v_{ce} = -\frac{\alpha_{cb}i_b}{G_L' + g_{ce}}\left(1 - \frac{\gamma i_b}{G_L' + g_{ce}} + \frac{\gamma^2 i_b^2}{(G_L' + g_{ce})^2} - \dots\right) =$$

$$-\frac{\alpha_{cb}i_b}{G_L' + g_{ce}}\left[\left(1 + \frac{3\gamma^2 I_{bs}^2)}{4(G_L' + g_{ce})^2}\right) \times \cos\omega t - \frac{\gamma I_{bs}}{2(G_L' + g_{ce})} - \frac{\gamma I_{bs}}{2(G_L' + g_{ce})} \times \cos 2\omega t + \frac{\gamma^2 I_{bs}^2}{4(G_L' + g_{ce})^2}\cos 3\omega t + \dots\right]$$

Neglecting higher order distortion terms

$$D_{0,2} \text{ per cent} \cong \frac{\gamma I_{bs}}{\sqrt{2}(G_L' + g_{ce})} 100$$

i.e., the distortion increases with I_{bs} and decreases with the increase of G_L' and of g_{ce}.

In a class-*A* transformer-coupled push-pull amplifier, assuming that the characteristics of the two transistors are identical, only odd-order harmonics are present. Therefore

$$D_3 \text{ per cent} \cong \frac{\gamma^2 I_{bs}^2}{4\left(g_{cc}+\dfrac{G_L'}{2}\right)^2}\,100$$

where $G_L = (N_2/N_1)^2 G_L$.

Numerical Example

Consider a transistor with the following specifications

$g_{bb}=3\times10^{-3}$ mhos, $g_{cc}=50\times10^{-6}$ mhos, $\alpha_{cb}=20$

$g_{bc}=0$, $I_b'=20$ microamperes, $I_0'=0.5$ milliampere, $I_{c\,max}=20$ milliamperes

$V_{ce}'=1$ volt, $V_{ce\,max}=40$ volts, $P_c=100$ milliwatts (at steady-state temperature)

Design a resistance-capacitance and a transformer-coupled amplifier for maximum power output (and maximum power gain) with given I_{bs} = 200 microamperes. With the resistance-capacitance configuration it is found that

$V_{ceQ}=18.5$ volts (equation 15), $E_c=17.5$ volts, $I_{cQ}=5.4$ milliamperes

$G_L=114\times10^{-6}$ mhos ($R_L=8{,}700$ ohms)

$G_2=64\times10^{-6}$ mhos ($R_2=15{,}600$ ohms)

$E_{cc}=102.5$ volts, $P_L=17.5$ milliwatts

It is noted that, if g_{cc} is neglected, equation 16 provides V_{ceQ} = 22 volts, with an error of 20 per cent in excess. The limit value of V_{ceQ} according to equation 3 is 20.5 volts.

With the transformer-coupled configuration

$V_{ceQ}=18.5$ volts, $E_c=17.5$ volts, $I_{cQ}=5.4$ milliamperes

$G_L'=178\times10^{-6}$ mhos ($R_L'=5{,}600$ ohms)

$E_{cc}=18.5$ volts, $P_L=27.4$ milliwatts

Consider now a push-pull configuration in class-*B* (*AB B*), with E_{cc} = V_{ceQ} = 18.5 volts. If I_{bQ} = 0, I_{cQ} = 0.05 milliampere; if I_{bQ} = 20 microamperes, I_{cQ} = 0.55 milliampere; the actual operating point is determined experimentally since the characteristics of the two transistors are never identical.

If I_{bs} is taken equal 400 microamperes

$E_c=17.5$ volts, $G_L'=406\times10^{-6}$ mhos, $P_L=62$ milliwatts

On the other hand the upper limit of I_s is $I_{c\,max}=20$ milliamperes so that the upper limit of I_{bs} is 0.97 milliampere. Correspondingly

$G_L'=1.14\times10^{-3}$ mho, $P_L=175$ milliwatts

Note that, if the upper limit of I_s could be taken equal $P_c/(1/\pi-1/4)E_{cc}=79$ milliamperes, a value $P_L=730$ milliwatts would result. The over-all and the input distortion are not considered here, but the collector distortion defined in the previous section will be evaluated with the assumption that $g_{cc}=0.2\ I_b$. In this case, for a single transformer-coupled amplifier

$$D_{0,2} \text{ per cent} \cong \frac{0.2\times200}{\sqrt{2}(178+0.2\times200)}\,100 = 13 \text{ per cent}$$

while for a class-*A* push-pull amplifier with I_b = 200 microamperes

$$D_3 \text{ per cent} \cong \frac{1}{4}\left(\frac{0.2\times200}{178+0.2\times200}\right)^2 100 = 0.8 \text{ per cent}$$

Appendix I. Explanation of Symbols

The equations of the linearized input and output characteristics of the common-emitter configuration

$$I_b=g_{bb}(V_{be}-V_{be}^0)+g_{bc}V_{ce} \qquad (1)$$

$$I_c=I_0'+\alpha_{cb}(I_b-I_b')+g_{cc}V_{ce} \qquad (2)$$

follow directly from the usual graphical representation; see Fig. 1. In equation 1, g_{bb} is the slope of the input characteristic curves and represents the input admittance with short-circuited output circuit, while g_{bc} is the reverse transfer admittance with short-circuited input circuit. In equation 2, α_{cb} is the forward current gain with short-circuited output circuit and g_{cc} is the slope of the output characteristic curves, i.e., the output admittance for the open input circuit. In addition, I_b' is the minimum base current consistent with the desired linearity ($|I_b'|\geq|I_{b\,min}|$), I_0', and V_{ce}' are shown in Fig. 1, and $I_0'-\alpha_{cb}I_b'$ is the collector current for $I_b=0$, $V_{ce}=0$. Finally, $I_c'=I_0'+g_{cc}V_{ce}$ is the collector current for $I_b=I_b'$.

In terms of the hybrid parameters of the common emitter (for large signal)

$$g_{bb}=\frac{1}{h_{11}},\quad \alpha_{cb}=h_{21},\ g_{bc}=-\frac{h_{12}}{h_{11}},\ g_{cc}=h_{22}$$

and in terms of the open-circuit parameters

$$g_{bb}\cong\left(r_b+\frac{r_e}{1-\alpha_{ce}}\right)^{-1},\ g_{cc}=[r_c(1-\alpha_{ce})]^{-1}$$

$$g_{bc}=-\frac{r_e}{r_c(1-\alpha_{ce})}\left(r_b+\frac{r_e}{1-\alpha_{ce}}\right)^{-1}$$

A Single-Transistor Magnetic-Coupled Oscillator

KAN CHEN
ASSOCIATE MEMBER AIEE

A. J. SCHIEWE
ASSOCIATE MEMBER AIEE

AN IMPORTANT oscillator circuit which converts d-c to a-c square waves having an output frequency proportional to the d-c input voltage was developed by Royer.[1] The circuit, shown in Fig. 1, employs a magnetic core constructed of square hysteresis loop material and two junction transistors operated as controlled switches.[2] As the circuit oscillates, the core flux swings repetitively between its positive and negative saturation levels, $\pm\phi_{max}$, the rate of flux excursion being proportional to the input voltage E_{in}. Thus, the frequency of oscillation is given by

$$f=\frac{E_{in}}{4N_1\phi_{max}} \qquad (1)$$

where N_1 is the number of turns of the windings in the collector circuit. Since the flux saturation levels ϕ_{max} vary with temperature, the output frequency is temperature-dependent. The output power is drawn from the input voltage source E_{in}, hence no power amplification is realized in this circuit.

Another oscillator circuit bearing a close resemblance to Royer's circuit was developed by Van Allen.[3] This circuit, shown in Fig. 2, employs two magnetic cores and two transistors, and produces also an a-c square wave having an output frequency proportional to the d-c input voltage. The general operating principle of Van Allen's circuit is similar to that of Royer's circuit.[3] However, there is a significant difference between the two circuits in consideration of the core flux excursion. Instead of swinging between saturation levels, the core flux in Van Allen's circuit is reset to an unsaturated value on alternate half-cycles in a manner similar to self-saturating magnetic amplifiers. This fact imparts to Van Allen's circuit the following advantages which justify the use of an additional core as compared to Royer's circuit:

1. The resetting action, and hence the frequency of oscillation, may be controlled by a current in an additional control winding at a low power level. Amplification of power is therefore achieved. The circuit offers the possibility of being operated as a frequency-modulated magnetic amplifier.

2. The additional means of controlling frequency provided by this current source facilitates frequency drift compensation.

3. The variation of flux saturation levels with temperature no longer has effect upon the frequency of oscillation, although variations of other core properties do.

The authors recognized the merits of Van Allen's circuit but were not completely satisfied with the explanation of the circuit operation given by Van Allen a critical study of which, substantiated by experimental results, precipitated the discovery that one half of Van Allen's or Royer's circuit would oscillate. The new oscillator circuit thus uses only one transistor and one core and retains the aforementioned merits of Van Allen's circuit. A fuller explanation of Van Allen's circuit and the description of the single-transistor magnetic-coupled oscillator follow.

Discussion of Van Allen's Circuit

Van Allen explains that the magnetic coupling of the two cores in his circuit permits one core to obtain a resetting voltage from the other core, which is being driven towards saturation. He is aware that the resetting core is not completely reset by the firing core because of the voltage drop across the rectifiers and winding resistances. He explains that these drops will determine to some extent the zero control current frequency. This is obviously true if one assumes that the circuit will sustain itself in oscillation. However, if these voltage drops were not compensated for, the cores would be reset less and less each cycle; hence, the circuit would eventually cease to oscillate for the conditions of zero or positive control current.

Experimental results obtained by the authors with the circuit of Fig. 2 lead to an explanation of the reset problem, an explanation based upon the factual existence of stray winding and transistor capacitances. It is believed that these stray capacitances, in particular those associated with the core windings, play a vital role in the mechanics of the resetting operation. Consideration of these capacitances leads to the following explanation of the operation of Van Allen's circuit for the condition of zero control current, and the cases for positive or negative control current follow directly from it.

Assume one of the transistors, Fig. 2, is conducting. The corresponding core is driven towards saturation, and at saturation a large surge of collector current takes place and, after this occurs, the transistor cuts off. This abrupt decrease of currents in the windings results in a large induced voltage (negative with respect to the induced voltage during the saturation period) across the core windings. If there were no stray capacitances in the circuit, the induced voltage would disappear as soon as the currents in the windings became zero. The resetting of the core would then depend entirely on the firing voltage available from the other core. However, the existing stray capacitances across the core windings and across the corresponding transistor tend to maintain this high induced voltage and cause the winding current to reverse direction. This action provides a negative exciting current and a proper volt-time area to reset the core partially. The frequency of oscillation will adjust itself so that the additional resetting action due to the stray capacitances is just enough to compensate for the loss due to voltage drops of part of the resetting volt-time area obtained from the firing core. The oscillograms in Fig. 3 show the large induced voltage across the windings at the beginning of the reset half-cycle. This induced voltage does not appear on the load because of the decoupling effect of the rectifiers.

The Single-Transistor Oscillator Circuit

With this reasoning, there appeared to be no reason why one half of Van Allen's circuit would not oscillate; see Fig. 4. That is, the core should be able to obtain sufficient resetting action for sustained oscillation from the stray capacitances, even for zero control current I_c. Of course, the frequency of oscillation would be determined by the magnitude of the stray capacitances and the magnitude of the load resistance. When this circuit was tested, the foregoing statements were

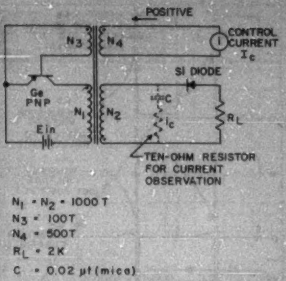

Fig. 4. Single-transistor magnetic-coupled oscillator with use of germanium p-n-p transistor

found to be true. The circuit oscillates without the rectifier in the load circuit. It is placed there to block the large negative induced voltage of the winding so that the output voltage will be rectangular. Winding voltage and rectifier voltage wave forms are shown in Figs. 5(A), 5(B), and 5(C). The negative spike on the load-voltage wave form appears because the Zener voltage of the rectifier has been exceeded. Since the firing voltage and the resetting voltage of the core are different in magnitude (and yet their volt-time areas must be equal), the firing and resetting periods are not equal.

The load voltage wave form may be made symmetrical by adjusting an external capacitance placed across any of the windings. The capacitance shown by dashed lines in Fig. 4 illustrates one possibility. The use of a large external capacitance has the accompanying advantages of swamping out the stray capacitances, which would be difficult to reproduce or to hold constant, and of reducing the peak negative induced voltage. Of course, the frequency of oscillation is lower than that of the stray capacitance case, because the amount of reset of the core flux is increased. The corresponding wave forms are shown in Figs. 6 and 7.

The theory of oscillation of this single-transistor circuit for zero control current may be more clearly stated in terms of the wave forms shown in Figs. 6 and 7. The load winding and the capacitor, Fig. 4, constitute a nonlinear tank circuit. The transistor is easily started into conduction by its own leakage through winding N_1 and the resulting positive voltage feedback action through the base winding N_3, if the load on the circuit is not excessive. Hence, the explanation of operation may be begun by assuming that the transistor is fully conducting. As the core flux reaches positive saturation and the transistor cuts off, the energy stored in the saturated inductance of the core is rapidly released, part being transferred to the capacitor and part being dissipated through core loss and resistance loss. This is revealed by the surge of capacitor current and the rapid reversal of the capacitor voltage, which reaches the negative peak in a very short time Δt, since the core remains saturated and the time constant is small during this period. As the capacitor forces energy back into the core, the core flux resets in the unsaturated level which results in a comparatively long time constant for this part of the transient. The damping of the tank circuit must be sufficiently small so that the winding voltage will overshoot and become positive again, Figs. 6(C) and 7(B), starting the next cycle of circuit oscillation by providing enough base drive for the transistor.

Of course, if the input voltage and the external capacitor are large enough, the energy stored in the capacitor at the beginning of the resetting half-cycle may be sufficient to reset the core to its negative saturation level. The winding voltage will then have a wave form as shown in Fig. 8(A). Once the core is saturated in the negative direction, the transistor is rendered conductive again by the fall-

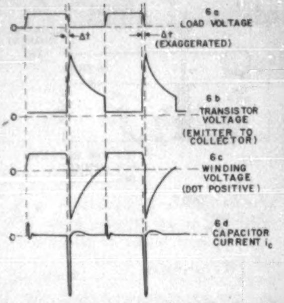

Fig. 6. Sketch of wave forms pertaining to single-transistor magnetic-coupled oscillator with external capacitor

back of the core flux to its negative remanence value, starting the next cycle of circuit oscillation.

When a control current I_c is present, the mechanics of core flux resetting operation is more complicated. In addition to varying the amount of reset of the core flux, the control current affects the wave form of the winding voltage during the resetting half-cycle through current transformer action. The negative winding voltage, which is also the capacitor voltage, will decay more or less rapidly, depending on whether the control current is positive (saturating) or negative (resetting). When a large negative control current is present, the magnitude of the negative winding voltage may actually increase with time until the core is saturated in the negative direction. The winding voltage will then have a wave form as shown in Fig. 8(B). It is therefore understandable that for some combination of values of the input voltage and the control current, the winding voltage may decay to zero before the core flux is reset to the negative saturation level. When this is the case, the transistor will remain nonconductive and oscillation of the circuit will cease.

In summary, the following two conditions have to be met in order that the single-transistor oscillator will commence and sustain oscillation:

1. The load resistor and the capacitor must not overload the oscillator during the saturating half-cycle, so that conduction of the transistor will be maintained by the current gain of the transistor and positive feedback through the magnetic coupling.

2. At the end of the resetting half-cycle, the winding voltage must be made positive enough to make the transistor conduct, either by an overshoot in an underdamped voltage transient, or by the fall-back of the core flux after it is driven to negative saturation.

Variety of Circuitry

A variety of circuits may be deduced from the basic single-transistor oscillator circuit in Fig. 4. For instance, the oscillator circuit may be used in a common base connection, as in Fig. 9. It becomes then identical to one half of the oscillator circuit which Uchrin and Taylor of the United States Signal Corps Engineering Laboratories claimed to have developed independently.[4] The germanium p-n-p transistor in Fig. 4 may be replaced by a silicon n-p-n transistor with a slight modification in circuit arrangement, as in Fig. 10. A diode is connected across the emitter and base of the silicon transistor in order to limit the emitter-to-base voltage within the maximum value of 1.5 volts specified by the manufacturer. A constant base drive voltage supplied by the input voltage E_{in} is necessary in this case to start the silicon transistor into conduction.

The output of circuits in Figs. 4, 9, and 10 is a train of d-c rectangular pulses, whose width and frequency may both be varied by adjusting the external capacitor, the input voltage and a current in an additional control winding (not shown in the last two figures). This kind of output is desired and is directly usable in many applications. When an a-c square wave is desired, the d-c output pulses from the single-transistor oscillator may be used to drive a push-pull transistor amplifier as shown in Fig. 11. In this arrangement the diode used in the previous circuits is no longer needed since the base-emitter junction of the transistor $T2$ acts in this capacity. The value of C may be adjusted to obtain any desired degree of symmetry in the a-c square-wave output.

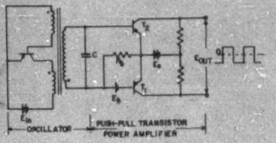

Fig. 11. (left) Converting d-c rectangular pulses to a-c square wave

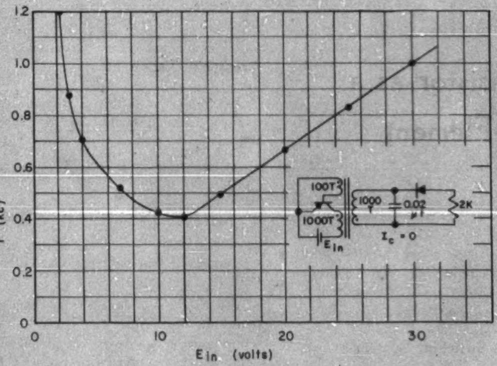
Fig. 12 (below). Variation of oscillator frequency as function of input voltage



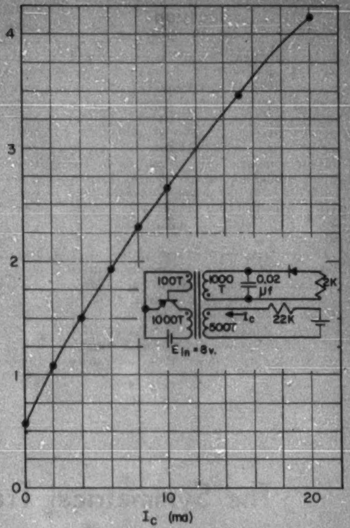


Fig. 13. Variation of oscillator frequency as function of control current

Experimental Results

The variation of frequency of the oscillator as a function of the input voltage, is shown by the curve in Fig. 12. Control of the oscillator frequency within a wide range by means of a positive or saturating control current is illustrated by the curve in Fig. 13. Notice, Fig. 12, that the frequency initially decreases with increasing input voltage. This is explicable since the amount of reset is directly related to the energy stored in the capacitor, which increases as the square of the input voltage, while the time required to drive the core flux from a certain level to saturation decreases only with the first power of the input voltage. The frequency reaches a minimum as the energy stored in the capacitor is just sufficient to reset the core to its negative saturation level. Beyond this point, the frequency increases linearly with the input voltage, as in Royer's circuit.

With a constant input of 8 volts to the circuit of Fig. 4 and no control current, the frequency changes considerably over a temperature range from room temperature to 71 degrees centigrade because the leakage current of the germanium transistor increases substantially at high temperatures, and the leakage current has significant effect on resetting of the core flux. However, the frequency of the circuit in Fig. 10, in which a silicon transistor is used, was found to change only 1/2 per cent over the same temperature range and at the same input voltage. This stability of frequency is attributed to the temperature stability of silicon transistors and the independence of the circuit frequency on the saturation levels of the core flux providing negative saturation is not reached.

Conclusion

A single-transistor magnetic-coupled oscillator has been developed and its principle of operation explained. It is hoped that the detailed circuit analysis has brought forth a fuller understanding of all types of magnetic-coupled oscillators and other similar circuits. The major advantage of the newly developed circuit is its simplicity in that only a single transistor and a single core are required. In addition, the circuit has good stability with temperature variations when silicon transistor is used, and its frequency may be controlled by the input voltage or by a current in a control winding, the latter giving a possible power gain.

(Discussion follows.)

Discussion

R. L. Van Allen (Naval Research Laboratory, Washington, D. C.): In the discussion of the variable frequency magnetic-coupled multivibrator, the paper indicates the effect of stray capacitance in maintaining oscillation, especially at zero control current. It is indeed necessary to consider this capacitance as a prerequisite to sustained oscillation at zero control current. The authors should be congratulated for discerning this fact and for applying this approach to a single-core single-transistor oscillator.

It is interesting that here at the Naval Research Laboratory a practically identical circuit was independently disclosed and investigated by H. T. Mortimer, formerly of the Naval Research Laboratory.[1] Besides describing a single-core single-transistor static converter, Mr. Mortimer's report contains a description and experimental results of a single-core single-transistor d-c to d-c amplifier. The principle of operation as a power amplifier is based on the utilization of an oscillator producing an asymmetric square wave which has a variable fundamental frequency. The waveform of this asymmetric square wave is such that the period of one half-cycle is relatively constant, while the period of the next half-cycle may be controlled as a function of a d-c control voltage. A d-c output is obtained in the form of pulses having constant height and width but with a repetition rate determined by the magnitude of the control voltage.

1. DC TO AC SQUARE-WAVE STATIC CONVERTER AND AMPLIFIER, H. T. Mortimer. *NRL Report No. 4582*, Naval Research Laboratory, Washington, D. C., July 27, 1955.

Harry T. Mortimer (Hallamore Electronics Company, Anaheim, Calif.): The authors are to be congratulated for their fine presentation of the single-transistor magnetic-coupled oscillator. Their comparison to Mr. Van Allen's circuits as well as the development of their ideas concerning the single transistor oscillator are clear and logical.

It is to be noted, in connection with the work reported here, that the writer had conceived circuitry equivalent in all respects to those reported in this paper. The conception and subsequent development of operating circuits date from November 1954. Development was continued, and led to a patent disclosure in March 1955. The writer's report (see reference 1 of Mr. Van Allen's discussion) fully developed the technical details and contained illustrations showing methods of operation and oscillograph wave forms. This work is considered a part of an unbroken continuation of the magnetic and transistor research program which supported Mr. Van Allen's work.

TRANSISTORS and diodes have been employed successfully as basic building blocks in the design of switching systems. Much progress is being made in the development of transistorized equipment which promises ultimately to supplant the more conventional electromechanical equipment that at present is in common use.

This paper discusses the use of a symmetrical transistor as a bidirectional switch useful in communications systems where very low insertion loss and high ON-OFF ratios are desired. Examples of the use of the switch as a convenient crosspoint as well as a brief analysis of the equivalent circuit and a derivation of circuit impedances leading to optimum performance will be shown.

A Simple Switching System

Fig. 1 is a block diagram of an elementary switching system which shows the use of co-ordinate signal path switch points. These switch points are closed or opened through the action of separate control circuits operating in response to supervisory signals. A simple system such as this can be expanded to larger proportions through the use of more lines and links, and through additional switching stages.

To establish a connection in the system of Fig. 1, it is necessary to close two crosspoints in one of the vertical columns. This completes a signal path between the corresponding two line terminals. A second simultaneous connection can be set up between two different lines through closure of two crosspoints in one of the other vertical columns and, in a similar manner, a third connection can be made through closure of two crosspoints in the remaining vertical column.

Crosspoint Requirements

A crosspoint element suitable for switching service should have the following characteristics:

1. A high degree of electrical isolation between control terminal and controlled terminals.
2. Negligible insertion loss when closed.
3. Negligible signal leakage when open.
4. Negligible load on input and output terminals when open.

Although a simple electromechanical relay possesses these characteristics, a semiconductor crosspoint can claim advantages such as small size and weight, low operating power, high speed, immunity to wear, corrosion, moisture, dirt, shock, and vibration, and, theoretically at least, infinite life.

The Bilateral Transistor Switch

An effective crosspoint can be made through the utilization of a bilateral transistor, as shown in Fig. 2. Bilateral transistors are symmetrical alloy junction germanium units of p-n-p or n-p-n configuration, in which either junction serves equally well as collector or emitter.

Fig. 3 shows the circuit detail of the 3-link system of Fig. 1, in which bilateral transistors are used as crosspoints in an unbalanced connection. The return sides of all lines are connected in common. This arrangement permits the use of a common transformer winding for all transistors in each row as well as a common choke for all transistors in each column.

Paper 56-585, recommended by the AIEE Solid State Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE North Eastern District Meeting, Rochester, N. Y., May 2–4, 1956. Manuscript submitted February 1, 1956; made available for printing April 25, 1956.

ROBERT B. TROUSDALE is with the Stromberg-Carlson Company, Rochester, N. Y.

The co-operation of many people at the Raytheon Manufacturing Company and the General Electric Company in the design and fabrication of bilateral transistors for application in Stromberg-Carlson switching equipment is gratefully acknowledged. Thanks are due to George Elliott, Stromberg-Carlson Company, for his contributions to the work leading to this paper. The research effort reported in this paper was shared by the Navy Bureau of Ships under contract *NObs-61658*.

It is interesting to note that d-c collector-operating potentials are not employed in the circuit.

Analysis of Bilateral Transistor Switch Operation

Referring again to Fig. 2(A), if it is assumed that the switch is in the OFF condition, then both junctions are biased in the reverse direction. The a-c impedance represented by each junction is very high and equal to the rate of change of the reverse-biasing voltage with respect to the reverse saturation current. The reverse impedances of the junctions are called r_c' and r_e' for the collector and emitter junctions respectively. It should be pointed out that, during the measurement of these reverse-biased junction impedances, the opposite junction is open-circuited.

Transmission in either direction through the switch is attenuated considerably in the OFF condition so long as the positive input signal peaks do not exceed the voltage of the base supply battery E_1. Under these conditions, the a-c equivalent circuit of the switch is as shown in Fig. 4. Typical values are

$R_1 = R_2 = 250$ ohms (source and load impedances)

$R_b = 10{,}000$ ohms

$r_e' = r_c' = 10$ megohms

for which the insertion loss is greater than 140 decibels, neglecting capacitance effects.

It has been found that the impedances of the junctions do not change materially with temperature and, for some germanium transistors tested, impedances measured at 55 degrees centigrade (C) have actually been higher than those at 25 C. When the switch of Fig. 2(A) is in the ON condition, then both junctions are biased in the forward direction, as emitters, and the base current divides about equally between the two. The magnitude of the base current is determined approximately by the ratio between the base supply battery potential E_2 and the base feed resistor R_b.

Assuming transmission from left to right, during positive alternations of the signal, the left-hand junction acts as an emitter and the right-hand junction acts as a saturated collector. Since the voltage drop between collector and emitter terminals of a saturated germanium alloy junction transistor is very small, the collector terminal will follow closely the voltage swings at the emitter terminal.

During negative alternations of the input signal, the left-hand junction acts as a collector and the right-hand junction as an emitter. The transistor will remain in saturation, and the right-hand terminal again closely follows the voltage swings at the left-hand terminal.

In a like manner, positive and negative alternations of a signal originating at the right-hand junction of the transistor are repeated at the left-hand junction. The switch, therefore, can handle signals in either direction and of either polarity, thus giving rise to the name "bilateral."

In developing equations relating transistor parameters and circuit constants to allowable signal levels while the switch is ON, it should be pointed out that the circuit is primarily intended to handle a wide variation in signal levels, including relatively large voltages and currents, and that the transistor is presumed to remain saturated over the entire signal cycle. This being the case, a rigorous analysis of the circuit operation which takes into account variations in transistor parameters as a function of collector or emitter current can become very complex and is assumed to be beyond the scope of this paper. For simplicity, therefore, it is assumed that the d-c switching β of the transistor is a constant and equal to

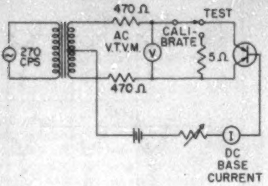

Fig. 5. Z_{ce} test circuit

1. Adjust oscillator to provide 5-millivolt reading on voltmeter when in calibrate position
2. Adjust base circuit resistor to obtain desired d-c base current
3. Read Z_{ce} directly from voltmeter when in test position. Scale factor is 1 ohm per millivolt

$$\beta=\frac{I_c}{I_b} \tag{1}$$

under conditions of collector current saturation. Interchanging the collector and emitter terminals, it may be assumed that the inverse d-c switching β' of the transistor is also constant and equal to

$$\beta'=\frac{I_e}{I_b} \tag{2}$$

under conditions of emitter current saturation. It will also be assumed that the junction voltage drops are small compared to the base supply battery potential E_2 and that the transistor base spreading resistance is a constant r_b. The transformers of Fig. 2(A) are assumed to be ideal.

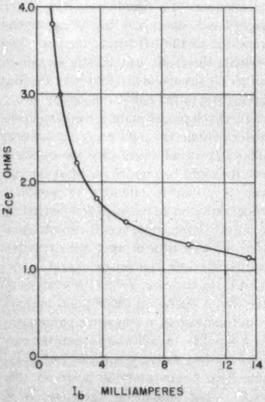

Fig. 6. Z_{ce} as a function of I_b

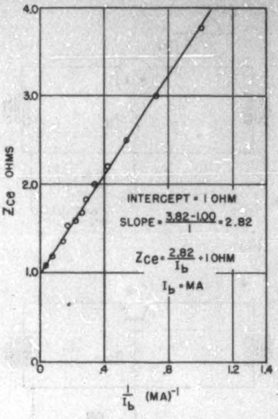

Fig. 7. Z_{ce} as a function of $1/I_b$

Under no-signal conditions, the base current is given by

$$I_b=\frac{E_2}{R_b+r_b} \tag{3}$$

If the signal swing is small compared to E_2, then the transistor will be capable of handling a peak signal current of

$$I_p=\beta I_b=\frac{\beta E_2}{R_b+r_b} \tag{4}$$

if the current flows into the emitter junction, and of

$$I_p=\beta' I_b=\frac{\beta' E_2}{R_b+r_b} \tag{5}$$

if the current flows into the collector junction. At currents in excess of these maxima, the transistor is driven out of its saturated region, and signal clipping or distortion occurs.

If the signal voltage is appreciable in comparison to E_2, as it normally is in practical circuits, equations 4 and 5 must be modified to include the change in base current caused by the signal itself. When a positive peak voltage e_p is applied to the emitter terminal, the base current is increased and the maximum peak signal current becomes

$$I_p=\beta I_b=\frac{\beta(E_2+e_p)}{R_b+r_b} \tag{6}$$

For negative voltages e_n applied to the emitter terminal, the transistor reverses polarity, the base current is reduced, and the peak signal current becomes

$$I_p=\beta' I_b=\frac{\beta'(E_2-e_n)}{R_b+r_b} \tag{7}$$

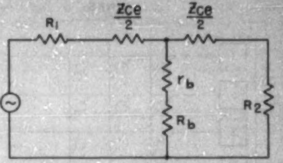

Fig. 8. Bilateral switch equivalent circuit, on condition

For a positive peak voltage e_p applied to the collector terminal, the transistor is still reversed, but the base current is now augmented

$$I_p=\beta' I_b=\frac{\beta'(E_2+e_p)}{R_b+r_b} \tag{8}$$

The last condition involves a negative voltage e_n applied to the collector terminal

$$I_p=\beta I_b=\frac{\beta(E_2-e_n)}{R_b+r_b} \tag{9}$$

If it is assumed that the forward β is equal to or greater than the reverse β', then, in general, equation 7 expresses the smallest value of the peak signal current I_p and is therefore the most limiting of the four equations 6, 7, 8, and 9.

It is desirable to utilize a transistor with high values of β and β' so that the switch may handle a given power level with small base currents and, therefore, high values of R_b. This decreases the shunting effect of R_b across the circuit and decreases the insertion loss. Experimental p-n-p bilateral transistors manufactured by Raytheon and General Electric have exhibited β values in excess of 20 in both directions.

It should also be kept in mind that E_2 must be sufficiently large that the degenerative effect of the input signal on the net base current may be kept within reasonable limits; see equations 7 and

Table I. Characteristics of a Raytheon-Type SC101 Transistor

I_{co} at 6 volts	3.6 microamperes
I_{co} at 25 volts	6.0 microamperes
I_{eo} at 6 volts	2.6 microamperes
I_{eo} at 25 volts	3.8 microamperes
r_c' at 6 volts	6.2×10^6 ohms
r_c' at 25 volts	8.3×10^6 ohms
r_e' at 6 volts	19.6×10^6 ohms
r_e' at 25 volts	3.8×10^6 ohms
Peak inverse voltage, collector junction	81 volts
Peak inverse voltage, emitter junction	93 volts
V_p, punch through	14 volts
Forward $-h_{11}$, 1 milliampere, 5 volts	0.977
Reverse $-h_{11}$, 1 milliampere, 5 volts	0.972
β at $I_c=10$ milliamperes	25.0
β'at $I_e=10$ milliamperes	22.3
Z_{ce} at $I_b=1$ milliampere	3.9 ohms

9. Before circuit design can be completed on a switch of this type, consideration must be given to the finite, though small, a-c series impedance existing between the two junctions.

If the forward and reverse d-c betas are equal, then the a-c impedance existing between the junctions is the same for either direction of current flow and is expressed as a function of base current by the following relation, assuming that the signal currents are small compared to the base current I_b

$$Z_{ce}=\frac{K}{I_b}+r_s \qquad (10)$$

where

K = a factor incorporating β, β', Boltzmann's constant, the temperature of the junction, and the electronic charge

r_s = the sum of the volume resistivities of the collector and emitter junctions

Ebers and Moll[1] have developed equations which act as theoretical bases for equation 10.

Fig. 5 shows a test circuit which provides a convenient means of determining Z_{ce} for symmetrical transistors. In the event that β and β' are unequal, the test circuit indicates the average of the impedance values for the two polarities. Thus, when considering the performance of the bilateral transistor in a network, it is presumed that linear circuit analysis may be performed employing the average Z_{ce} reading, with the understanding that differences between β and β' will give rise to a small amount of harmonic distortion.

Fig. 6 is a curve of Z_{ce} plotted against I_b for a typical Raytheon bilateral transistor. These data were obtained from the test circuit of Fig. 5. Replotting the curve with $1/I_b$ as the abscissa, a straight line is obtained, as shown in Fig. 7. The slope of this curve is the constant K and the intercept is the constant r_s of equation 10. The empirical equation for Z_{ce} of this transistor can then be written as

$$Z_{ce}=\frac{2.82}{I_b}+1.0 \text{ ohm} \qquad (11)$$

where I_b is in milliamperes. This is in approximate agreement with Ebers and Moll,[1] who point out further that the constant K bears an inverse relationship to β and β'. Typical values of Z_{ce} in bilateral transistors measured to date range from 3 to 8 ohms at a base current of 1 milliampere.

The bilateral transistor exhibits gain in so far as the control bias is concerned, thus permitting effective isolation of the signal path from the control source through the use of a relatively large base current feed resistor. The transistor, however, does not amplify the signal itself and, therefore, it is desirable to choose operating impedances which result in the lowest possible insertion loss. To accomplish this, reference is made to Fig. 8, in which the equivalent circuit of the switch in the ON condition is shown. Z_{ce} is arbitrarily split into two equal components, representing the two identical junctions, and the variation of Z_{ce} with base current is made negligible by assuming small signal voltages. The base spreading resistance r_b is very small compared to R_b in practical circuits and can be neglected.

Since the transmission path is bidirectional, the source and load impedances R_1 and R_2 are equal, these being representative of two identical telephones, for example. The transistor can now be looked upon as a 4-terminal network possessing a transfer function which will be closest to unity when the source and load impedances are made equal to the image impedance of the network

$$Z_I=\sqrt{Z_{oc}Z_{sc}}$$

$$=\sqrt{\left(\frac{Z_{ce}}{2}+R_b\right)\left[\frac{Z_{ce}}{2}+\frac{Z_{ce}R_b}{2\left(\frac{Z_{ce}}{2}+R_b\right)}\right]}$$

$$=\sqrt{\frac{Z_{ce}^2+4R_bZ_{ce}}{4}}$$

Since $R_b>>Z_{ce}$ in most practical circuits, this reduces to

$$Z_I=\sqrt{R_bZ_{ce}} \qquad (12)$$

If, for example, a 10,000-ohm R_b is employed with a transistor exhibiting a Z_{ce} of 5 ohms, then the source and load impedances should be made equal to

$$R_1=R_2=\sqrt{10{,}000\times 5}=224 \text{ ohms}$$

This impedance may be realized by the proper choice of turns-ratio for the line transformers in Fig. 3. The link chokes serve merely as d-c returns and do not exhibit appreciable a-c shunt loss.

The insertion loss exhibited by the switch of the foregoing example is derived from the transfer function of the network as follows:

$$\text{transfer function without switch}=\frac{R_1}{2R_1}=0.5$$

transfer function with switch

$$=\left(\frac{R_1}{R_1+\frac{Z_{ce}}{2}}\right)\left(\frac{R_1-\frac{Z_{ce}}{2}}{2R_1}\right)=0.5\frac{(2R_1-Z_{ce})}{(2R_1+Z_{ce})}$$

The factor $(2R_1-Z_{ce})/(2R_1+Z_{ce})$ is the insertion gain of the switch, the reciprocal of which is the insertion loss

$$\frac{2R_1+Z_{ce}}{2R_1-Z_{ce}}=\frac{448+5}{448-5}=\frac{453}{443}=0.194 \text{ decibel} \qquad (13)$$

Since the switch is terminated in its image impedance, several such switches may be cascaded without change in the optimum source and load impedance levels, the resulting insertion loss being determined by multiplying the decibel insertion loss per stage by the number of stages.

To bring out more fully the unique characteristics of transistors specifically designed for use as crosspoint switches, Table I shows the characteristics of a typical Raytheon-type *SC101* bilateral transistor.

Summary

The symmetrical germanium alloy junction transistor has been found to be a very satisfactory bidirectional switch for use in electronic switching systems. It provides circuit isolation between the signal path and the control source, and can handle signals of either polarity. With the switch open, signal leakage is down more than 100 decibels even at high temperatures, and insertion losses of less than 0.2 decibel can be obtained with the switch closed. The degree of circuit isolation, the insertion loss, and the power-handling capacity can all be improved through the use of transistors with high forward and reverse current gains.

An Analysis and Design of the Ferroelectric Resonant Trigger Pair

CHARLES E. GREMER
NONMEMBER AIEE

THE CIRCUITS to be analyzed in this paper are the 2-branch series-resonant circuit shown in Fig. 1; and the 2-mesh, parallel resonant circuit shown in Fig. 2. There are several approaches for analyzing such circuits based upon developments by Duffing, Poincaré, Kryloff and Bogoliuboff and others.[1-9] The choice of one approach over another depends on the accuracy desired, the accuracy obtainable, and the exact problem confronting the analyst. It should be noted that all of the known analytical methods suffer from one inherent disadvantage: they produce solutions for only the case under consideration without any hint as to the totality of solutions available. A qualitative method, known as the topological approach, gives an over-all picture of the totality of solutions but yields no specific information on any particular case.[3,5,6]

In any circuit containing nonlinearities, it must be decided what function will represent the nonlinearity before the problem is commenced. Since this paper concerns itself with the nonlinear capacitor as its vehicle of operation, a charge function of the voltage across the capacitor terminals is desired. Now it is known a priori that two states are to exist for the branches: 1. a large current condition, and 2. a small current condition. Since it is desired to obtain the criteria for such states, and since these two states depend on whether or not the branch is in nonlinear resonance, the primary interest in the charge-voltage relationship is not their actual point-by-point correspondence, but rather an average of the initial and an average of the final charge-voltage slopes of the loop tip locus.

Now since a single-valued function is to be specified and it is actually known that the relationship is double-valued for any given driving voltage, accuracy will be forfeited *ab initio*. It is thus fortuitous to choose a rather simple function which still defines, within limits, the circuit operation.

The function chosen is

$$e(q)=a_1q+a_3q^3 \qquad (1)$$

where a_1 and a_3 are constants to be determined by measurements on the nonlinear capacitor. Obviously, any odd function which approximates the $e(q)$ relation could be used. However, owing to the initial assumptions, it is believed that nothing greater than a cubic is warranted.

Two-Branch Series-Resonant Circuit

THE LOSS-FREE CIRCUIT

The circuit equations for Fig. 1 can be written

$$q_s=q_1+q_2 \qquad (2)$$

$$L(\ddot{q}_1-\ddot{q}_2)+e_1-e_2=0 \qquad (3)$$

Using equation 1, equation 3 becomes

$$(\ddot{q}_1-\ddot{q}_2)+\frac{a_1}{L}(q_1-q_2)+\frac{a_3}{L}(q_1^3-q_2^3)=0 \qquad (4)$$

At this point a mathematical artifice is introduced. Equation 4 is first solved for the difference differential and a term ω^2-(q_1-q_2) is then added to both sides of this equation. This procedure results in the final form of the circuit equation

$$(\ddot{q}_1-\ddot{q}_2)+\omega^2(q_1-q_2) =\left(\omega^2-\frac{a_1}{L}\right)(q_1-q_2)-\frac{a_3}{L}(q_1^3-q_2^3) \qquad (5)$$

Now, the procedure is one of iteration, where an approximation is substituted into the right-hand side of equation 5 and the left-hand side is solved for the steady-state periodic solution.

The first approximation begins with

$$q_{10}=A \sin \omega t \text{ and} \qquad (6)$$
$$q_{20}=B \sin \omega t$$

where the second subscript denotes the iteration by which the value was obtained.

Equation 5 thus becomes

$$(\ddot{q}_1-\ddot{q}_2)+\omega^2(q_1-q_2) =\left[\left(\omega^2-\frac{a_1}{L}\right)(A-B)-\frac{3a_3}{4L}\times (A^3-B^3)\right] \sin \omega t+ \frac{a_3}{4L}(A^3-B^3) \sin 3\omega t \qquad (7)$$

Since $a_3>0$, only periodic solutions will be available.[6] Invoking the condition for periodicity (i.e., due to the $\omega^2(q_1-q_2)$ term, the coefficient of sin ωt must vanish or else secular terms will appear in the solution), there results

$$\left(\omega^2-\frac{a_1}{L}\right)(A-B)-\frac{3a_3}{4L}(A^3-B^3)=0 \qquad (8)$$

Disregarding the trivial case, $A=B$, and from equation 2 there result two equations relating A and B. These are the following

$$\psi_1\equiv 0=-Q_s+A+B \qquad (9)$$

$$\psi_2\equiv 0=-S+m(A^2+AB+B^2) \qquad (10)$$

where

$$S=(\omega/\omega_0)^2-1 \qquad (11)$$

$$\omega_0^2=a_1/L \qquad (12)$$

$$m=3a_3/4a_1 \qquad (13)$$

The only information available from ψ_1 and ψ_2 is that for ψ_2 to be a real ellipse $S\overset{M}{>}0$, and hence $\omega\overset{M}{>}\omega_0$, where the symbol $\overset{M}{>}$ means "must be greater than."

After the condition for periodicity has been invoked, equation 7 is then solved and there is thus obtained

$$(q_1-q_2)_1=K \sin \omega t- \frac{a_3}{32\omega^2L}(A^3-B^3) \sin 3\omega t \qquad (14)$$

It is now assumed that the constant of integration K is equal to the factor $A-B$. There is thus obtained by equating the portions of this equation identifiable with q_1 and q_2 respectively

$$q_{11}=A \sin \omega t-DA^3 \sin 3\omega t \qquad (15A)$$

$$q_{21}=B \sin \omega t-DB^3 \sin 3\omega t \qquad (15B)$$

where

$$D=\frac{a_3}{32\omega^2L}=\frac{m}{24(S+1)} \qquad (16)$$

These relationships are now substituted into the right-hand side of equation 5 and the condition for periodicity again invoked. Disregarding the trivial solution, $A=B$, there results

---

Paper 56-119, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956; and re-presented at the North Eastern District Meeting, Rochester, N. Y., May 2–4, 1956. Manuscript submitted June 27, 1955; made available for printing March 14, 1956.

LT. CHARLES E. GREMER is at the U. S. Naval Shipyard, Charleston, S. C.

The author wishes to thank Dr. Charles F. Spitzer, of the General Electric Company, who first suggested work on the problem presented, and who discussed the solutions. Gratitude is also expressed to the General Electric Company, Syracuse, N. Y., for providing laboratory space and equipment. The project was completed as a partial requirement for a United States Naval Postgraduate School M.S. degree, Monterey, Calif. In this connection thanks are due Prof. Carl E. Menneken and Capt. Paul Van Leunen of the Naval Postgraduate School; also C. P. Gade and C. A. Rosen of the General Electric Company for arranging the industrial tour where the project was accomplished.

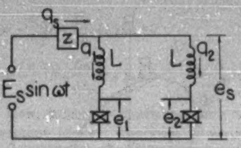

Fig. 1. Two-branch nonlinear series-resonant circuit

$$\psi_3 \equiv 0 = -S + m(A^2+AB+B^2) + mD(A^4+A^3B+A^2B^2+AB^3+B^4) + 2mD^2(A^6+A^5B+A^4B^2+A^3B^3+A^2B^4+AB^5+B^6) \quad (17)$$

To simplify the solution of equation 17 and to determine more easily whether or not it has only one real root, the rotation matrix

$$\begin{Vmatrix} A \\ B \end{Vmatrix} = \begin{Vmatrix} \sqrt{\tfrac{1}{2}} & -\sqrt{\tfrac{1}{2}} \\ \sqrt{\tfrac{1}{2}} & \sqrt{\tfrac{1}{2}} \end{Vmatrix} \times \begin{Vmatrix} \alpha \\ \beta \end{Vmatrix} \quad (18)$$

and the linear transformation

$$\alpha = \rho \cos \theta \quad (19A)$$

$$\beta = \rho \sin \theta \quad (19B)$$

are applied to equation 17, which results in

$$\psi_3 = 0 = -S/m + {}^1/_2 f(\theta)\rho^2 + {}^1/_4 Dg(\theta)\rho^4 + {}^1/_4 D^2 h(\theta)\rho^1 \quad (20)$$

where

$$f(\theta) = 2 + \cos 2\theta \quad (21)$$

$$g(\theta) = 3.5 + 2 \cos 2\theta - {}^1/_2 \cos 4\theta \quad (22)$$

$$h(\theta) = 15 + \cos 2\theta[4 - 18 \cos 2\theta - \cos^2 2\theta] + 7 \cos 4\theta \quad (23)$$

For any θ, ψ_3 has only two finite, real roots (positive and negative values of the same magnitude) and hence represents a single, closed loop. Thus equation 20 need be solved for only one value of ρ^2, and hence ρ, for each θ. ψ_1, ψ_2, and ψ_3 are shown in Fig. 3.

From Fig. 3 the mode of operation may be explained. For small values of E_s, and hence Q_s, the two series branches behave as linear networks and thus A equals B. As E_s is increased, ψ_1 moves out from the origin, remaining parallel to the β axis. The operating point remains on the intersection of ψ_1 and the α axis. It can be shown that ψ_1 will be tangent to ψ_3 at P_1. When ψ_1 does become tangent to ψ_3 by increased Q_s, two other points of operation are available: P_2 and P_3. Although no mathematical proof is given here, it can be deduced from the work of Stoker that operation in the area around P_1 is unstable.[6]

The value of source current required to reach bistability condition can be solved from equation 20 and equation 2. It is given by

$$I_s = \omega Q_s \quad (24)$$

$$Q_s = \sqrt{2}\rho(\theta = 0°) \quad (25)$$

$$\rho(\theta = 0°) = \frac{0.756}{\sqrt{D}}(1.68 \sinh u - 0.417)^{1/2} \quad (26)$$

$$u = \frac{1}{3} \sinh^{-1} \frac{0.915S + 0.805}{S+1} \quad (27)$$

Obviously, if ψ_1 moves out so far that it fails to intersect ψ_3, bistability fails to exist and both branches revert to equal but large currents. This value can be obtained by finding the appropriate point besides P_1 where $d\alpha/d\beta$ vanishes. In view of the original approximations, this current can be obtained to a sufficient degree of accuracy from a plot such as Fig. 3.

Low Loss Circuit

Attention is now given to the case where the two branches contain low losses. Equation 5 is rewritten to include the effect of resistance as follows

$$(\ddot{q}_1 - \ddot{q}_2) + \omega^2(q_1 - q_2) = \left(\omega^2 - \frac{a_1}{L}\right)(q_1 - q_2) - \frac{R}{L}(\dot{q}_1 - \dot{q}_2) + \frac{a_3}{L}(q_1^3 - q_2^3) \quad (28)$$

Assuming that R is small compared to Z_1, then I_s will still be primarily determined by Z_1. For the remainder of the 2-branch series-resonant discussion, it will be assumed that $A \gg B$. The first iteration begins with the approximations

$$q_{10} = A \sin \omega t \quad (29A)$$

$$q_{20} = B \sin (\omega t - \phi) \quad (29B)$$

Using these values in the right-hand side of equation 28 and application of the periodicity conditions results in the modified ellipse ψ_2' where it has been assumed that $S \gg mB^2$

$$\psi_2' \equiv 0 = A^2 + AB + B^2 - S/m + \frac{2_R2}{a_1^2 Sm} \quad (30)$$

Now, ψ_2' will not be a real ellipse and hence bistability cannot result unless

$$R < a_1 S/\omega \quad (31)$$

Under the assumption that $B \approx 0$, the following relations can be derived

$$A = \sqrt{\frac{S}{m} - \frac{\omega^2 R^2}{a_1^2 Sm}} \quad (32)$$

$$B = \frac{\omega R}{a_1 S} A \quad (33)$$

$$\Delta = A/B = \frac{a_1 S}{\omega R} \quad (34)$$

$$E_1 = a_1 A + a_3 A^3 \quad (35)$$

$$E_2 = a_1 B \quad (36)$$

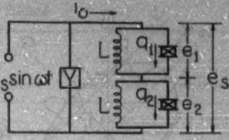

Fig. 2. Two-mesh nonlinear parallel resonant circuit

From these equations two important relations between the sampling voltages, E_1 and E_2, can be obtained. These are the difference between the two sampled voltages and the ratio of the two sampled voltages. This difference determines the quality of the bistable circuit, or at least the ability to distinguish between the two stable states. With a little mathematical manipulation there is obtained

$$E_1 - E_2 = \left[a_1(1+S) - \frac{\omega R}{S}\left(\frac{\omega R}{a_1} - 1\right)\right] \times \sqrt{\frac{S}{m} - \frac{\omega^2 R^2}{a_1^2 Sm}} \quad (37)$$

$$E_1/E_2 = \Delta\left(1 + S - \frac{S}{\Delta^2}\right) \quad (38)$$

The smaller the value of m is the larger the potential difference between the nonlinear capacitors is for a given Δ. This follows from equation 37 and the fact that Δ is related to the parameter S by equation 34. This potential difference, however, is obtainable only by making A increase its value over B. But since the switching ratio Δ was prescribed, both A and B increase. Although Δ, itself, is independent of m, it must be remembered that too small a nonlinearity results in currents of such magnitude that the components may be destroyed before the bistability conditions can be reached.

The second iteration procedure modifies these relations somewhat and emphasizes the choice of m. It can be shown that the nonlinearity should be such that

$$\frac{S}{S - mB^4} \geq \Delta > 1 \quad (39)$$

does not require B so large that the component ratings are exceeded by the value of A.

Two-Mesh, Parallel Resonant Circuit

The 2-mesh, parallel resonant case can now be treated with less detail. From Fig. 2 the following equations can be written

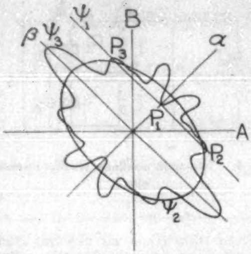

Fig. 3. First and second iteration solution curves for series-resonant circuit

$$i_0=\frac{1}{L}\int e_1dt+\dot{q}_1 \tag{40}$$

$$i_0=\frac{1}{L}\int e_2dt+\dot{q}_2 \tag{41}$$

Subtracting equation 41 from equation 40 there results

$$\frac{1}{L}\int(e_1-e_2)dt+(\dot{q}_1-\dot{q}_2)=0 \tag{42}$$

Since there are no d-c sources in the circuit, no loss of generality occurs if equation 42 is differentiated with respect to time. This results in

$$(\ddot{q}_1-\ddot{q}_2)+\frac{1}{L}(e_1-e_2)=0 \tag{43}$$

The other basic equation is

$$e_1+e_2=e_s \tag{44}$$

In lieu of the constant current source, a constant voltage source is prescribed, and hence i_0 is a small quantity. For lossless circuits, e_1 and e_2 both lag i_0 by 90 degrees if $\omega>\omega_0$. The charge will be in phase with the voltage, and the first approximations can be written as

$$q_{10}=A\cos\omega t \tag{45A}$$

$$q_{20}=B\cos\omega t \tag{45B}$$

Proceeding as with the series-resonant case, the two solution curves relating A and B are found to be

$$\psi_2\equiv 0=-S+m(A^2+AB+B^2) \tag{46}$$

$$\psi_4\equiv 0=-\frac{E_s}{a_1}+(A+B)+m(A^3+B^3) \tag{47}$$

It is to be noted that ψ_2 is common to both systems, but that the straight line ψ_1 has now become the cubic ψ_4. The fact that ψ_4 is a cubic, as shown in Fig. 4, makes it possible to demonstrate bistability from the first iteration. The operating point for low values of E_s is on the intersection of ψ_4 and the line $A=B$. As E_s is increased, ψ_4 moves away from the origin, its asymptotic line remaining parallel to the line $A=-B$. When ψ_4 becomes tangent to ψ_2 at P_1, the operating point "jumps" from P_1 to either P_2 or P_3.

The half-axes of the ellipse are

$$a_\alpha=\sqrt{\frac{2S}{3m}} \tag{48}$$

$$a_\beta=\sqrt{\frac{2S}{m}} \tag{49}$$

The first of these represents the "distance" from the origin to P_1. Since $A=B$ at this point

$$A=\sqrt{\frac{S}{3m}} \tag{50}$$

Substituting this value in equation 47 results in

$$E_s=2a_1\left(1+\frac{S}{3}\right)\sqrt{\frac{S}{3m}} \tag{51}$$

as the source voltage required for bistability. This value of E_s has another interpretation which may be obtained from a study of Fig. 4. If E_s were larger than this value, then there is the possibility of having two sets of bistable operating points. Thus for no more than two stable operating points

$$E_s\leq 2a_1\left(1+\frac{S}{3}\right)\sqrt{\frac{S}{3m}} \tag{52}$$

As E_s is further increased, there is a value beyond which bistability will cease and reversion to the $A=B$ condition occurs. This value of E_s is found by determining the common point of tangency between ψ_2 and ψ_4 besides the one already found at P_1. For ψ_2 and ψ_4 to osculate at a given point, the following conditions must be satisfied at the point

$$\frac{\partial\psi_2}{\partial A}=\frac{\partial\psi_4}{\partial A} \tag{53A}$$

$$\frac{\partial\psi_2}{\partial B}=\frac{\partial\psi_4}{\partial B} \tag{53B}$$

These give

$$1+3mA^2=m(2A+B) \tag{54}$$

$$1+3mB^2=m(2B+A) \tag{55}$$

Division of these two equations, simplification and omission of the $A=B$ solution results in

$$\psi_5\equiv 0=A^2+3AB+B^2-\frac{1}{3m} \tag{56}$$

Application of the rotation matrix, equation 18 produces a hyperbola

$$\psi_6\equiv 0=5_\alpha{}^2-\beta^2-\frac{2}{3m} \tag{57}$$

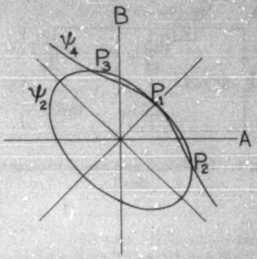

Fig. 4. First iteration solution curves for parallel resonant circuit

with half-axes

$$b_\alpha=\sqrt{\frac{2}{15m}} \tag{58}$$

$$b_\beta=\sqrt{\frac{2}{3m}} \tag{59}$$

The ellipse ψ_2 and the hyperbola ψ_6 will intersect if the half-axes obey the relations

$$b_\alpha<a_\alpha,\text{ or }\sqrt{\frac{2}{15m}}<\sqrt{\frac{2S}{3m}} \tag{60}$$

From this inequality another criterion for bistability results

$$S>1/5,\text{ or} \tag{61}$$

$$\omega^2/6\omega_0{}^2/5 \tag{62}$$

A second iteration can be considered and accomplished as for the series-resonant circuit: likewise, the low loss case can be treated, all of which has been done, but the results are omitted here in order to present another method of obtaining the bistability criteria.[10]

A Second Method for Bistable Current

Instead of writing equation 3, the branch equations can be written as

$$e_0=L\dot{q}_1+e_1 \tag{63}$$

$$e_0=L\dot{q}_2+e_2 \tag{64}$$

where e_0 is as shown in Fig. 1 and is also given by

$$e_0=e_s-e_z(q_1+q_2) \tag{65}$$

the term $e_z(q_1+q_2)$ being a linear function representing the voltage drop across Z. From the first iteration assumptions, e_0 is of the form $E_0\sin t$ to a first approximation. Hence, upon modifying equation 63 and equation 64 as was equation 5; and after application of the periodicity conditions there is obtained

$$\left(\omega^2-\frac{a_1}{L}\right)A-\frac{3a_3}{4L}A^3+E_0=0 \tag{66}$$

$$\left(\omega^2-\frac{a_1}{L}\right)B-\frac{3a_3}{4L}B^3+E_0=0 \tag{67}$$

Now, Stoker has shown that for a first iteration, at least, the locus of vertical tangents of the curves defined by equation 66 or equation 67 are unstable.[6] The locus is found by letting $d\omega/dA$ (or $d\omega/dB$) vanish. The result is, for equation 66, the following

$$S-3mA^2=0 \tag{68}$$

from which

$$A=\sqrt{\frac{S}{3m}} \tag{69}$$

which is the same value as given by equation 50.

Thus the first iteration value of required bistability current can be obtained by consideration of one branch alone. The same procedure holds true for the second iteration. Application of the periodicity conditions to this approximation gives

$$SA-mA^3-mDA^5-2mD^2A^7+\frac{L}{a_1}E_0=0 \tag{70}$$

Letting $d\omega/dA$ vanish produces the following result

$$\frac{S}{m}-3A^2-5DA^4-14D^2A^6=0 \tag{71}$$

If the value $B=A$ is set into equation 17, the same result is obtained. Thus if the hypothesis is accepted that the locus of vertical tangents is also a locus of unstable points, then the reasoning that leads to equation 24 through equation 27 is correct. Conversely, the required value of current (or voltage) can be obtained by considering one branch alone. However, such items as switching ratio and loss limitations are not readily available.

Conclusions

Special note should be made of the fact that the switching ratio is independent of the degree of nonlinearity. However, too small a nonlinearity may result in currents which cause the components to be destroyed. On the other hand, too large a nonlinearity could cause the output voltages to be too small for use. Experimental evidence confirms the validity of equation 24 through equation 27 within the accuracy of component values.[10] Table I gives a brief résumé of these results. The component values were measured at 20 kc, the highest frequency at which measurements could be made on the nonlinear capacitors during the time alloted to the experiments.

The Ferroresonant Trigger Pair: Analysis and Design

CHARLES F. SPITZER
MEMBER AIEE

Synopsis: The phenomenon of nonlinear resonance can be utilized in the design of a trigger pair which uses neither vacuum tubes nor transistors, is capable of high-speed operation, and operates with electrical input and output signals. This article outlines the analysis of the basic circuit to a first approximation only, and design relations are derived. Experimental data are also given. Applications of the circuit described may be found in the logic components of digital data-handling apparatus.

IF, IN A LOW-LOSS series resonant circuit, Fig. 1(A), one or both energy storage elements are nonlinear, and the system is supplied from an a-c power source of suitable voltage and frequency, then the effective value of the resultant nonsinusoidal current may have either of two possible values; see Fig. 1(B). Thus, basically, this circuit can be used as a single-ended bistable element: the output is either high or low.

If two such nonlinear circuits are connected in parallel, and the system is supplied from a power source of suitable current and frequency, then the source cur-

Paper 56-584, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE North Eastern District Meeting, Rochester, N. Y., May 2–4, 1956. Manuscript submitted July 1, 1955; made available for printing February 24, 1956.

Charles F. Spitzer is with General Electric Company, Syracuse, N. Y.

This paper is condensed from a dissertation on ferroresonant circuits for digital computers, presented to the Yale University School of Engineering in partial fulfillment of the requirements for the degree of doctor of engineering. The work was carried out at the Electronics Laboratory of the General Electric Company's electronics division, Syracuse, N. Y.

The author expresses sincere appreciation to Dr. L. C. Meier and Charles A. Rosen for their permission to utilize facilities of the electronics laboratory for some of the work, and to Dr. John M. Blank for supplying the ferrite cores used in the experiments. The continued interest and advice given by Prof. P. F. Ordung of Yale University are gratefully acknowledged.

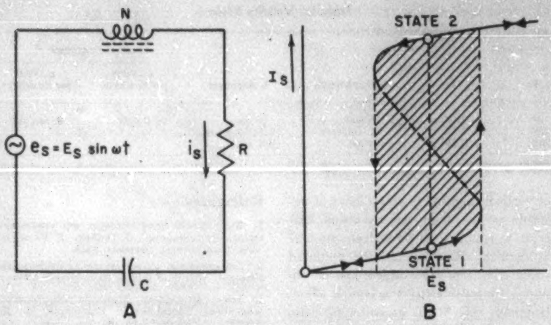

Fig. 1(A)—Basic nonlinearly resonant series circuit, with saturable core. (B)—Response of the basic nonlinearly resonant series circuit of (A)

rent flows almost entirely in either one branch or the other. Thus, this circuit can be used as a double-ended bistable element: the output of one branch is high, when the output of the other branch is low, and vice versa; see Figs. 2 and 3. Triggering can be achieved in a variety of ways, either by means of electrical signals (current pulses through trigger windings) or magnetic signals directly introduced into one or the other core, or into both cores simultaneously.

Suitably designed, the circuit of Fig. 2 can thus be used as the basic unit for binary counters, for storage registers, for gates, and for a variety of other logic components for digital data-handling systems. Triggering for this application is usually achieved most conveniently by successive like-polarity pulses, applied either to a common trigger coil surrounding the nonlinear cores of the two branches, or to the terminals of a series connection or parallel connection of two trigger coils, each of which surrounds the nonlinear core of one of the two branches.

The manner of triggering and the power requirements to achieve it are not the subject of this paper. Rather, it is desired to determine those parameter relations of the basic double-branch circuit, which will maximize the ratio of the branch currents, and therefore result in optimum design for the applications just listed.

The basic ferroresonant trigger pair is shown schematically in Fig. 2, and consists of a parallel arrangement of two series circuits, each containing a capacitor and a nonlinear inductor. The power source is a constant-voltage generator in series with a suitable impedance, such as capacitor C_2. This circuit appears to have been independently developed by Isborn,[1] and by this author and Robert J. Reich.[2]

The underlying phenomenon of nonlinear resonance was reported as early as 45 years ago,[3] and has been the object of study for many years.[4-6] A survey of the literature on nonlinear resonance discloses that the exact mathematical analysis of even the basic 1-mesh nonlinear series circuit is relatively involved.[7-10] The more complicated 2-mesh nonlinear device appears discouraging, from the viewpoint of rigorous analysis. From a practical viewpoint, however, one must realize that the first premise, i.e., that of a simple mathematical description of the nonlinearities in the circuit, seriously and a priori abrogates the accuracy of the result, and no amount of rigor in subsequent steps can compensate for the errors introduced by the initial assumptions. It is therefore the purpose of this paper to outline a simplified analysis of the double-branch series-ferroresonant trigger circuit, to a first approximation only. The fundamental components of voltages and currents are considered, and all harmonics are disregarded, in the evolution of design equations of sufficient simplicity and accuracy to be useful to the engineer constructing a trigger pair. It is believed that this initial objective has been reached. If desired, however, better accuracy can be achieved by use of the well-known iteration method,[7,8] for which the subsequent results represent the first approximation.

The assumption that the fundamental component is sufficiently predominant to permit the exclusion of all harmonics in this analysis can perhaps be made almost acceptable. It will be seen later that a small degree of nonlinearity causes the output voltage to become refreshingly large, even though this is accompanied by relatively large currents throughout the system. This does not imply that the harmonics of all currents and all voltages are always negligible, as is readily seen in the oscillograms of Fig. 4 for example, but the small degree of nonlinearity nevertheless lends some small measure of justification to the procedure.

Nomenclature

All units are in the rationalized meter-kilogram-second system.

a_1, a_3 = coefficients in the flux-current relationship
a_α, a_β = major and minor axes of operating ellipse
b_α, b_β = major and minor axes of limiting hyperbola
A = peak value of flux in core of coil carrying larger of two branch currents
B = peak value of flux in core of coil carrying smaller of two branch currents
C_1 = capacitance in series with a-c source
C_2 = capacitance in each of two parallel branches
e_0, E_0 = instantaneous and peak values of branch voltage
e_1, E_1 = instantaneous and peak values of larger of two output voltages
e_2, E_2 = instantaneous and peak values of smaller of two output voltages
e_s, E_s = instantaneous and peak values of a-c source voltage
i_1, I_1 = instantaneous and peak values of larger of two branch currents
i_2, I_2 = instantaneous and peak values of smaller of two branch currents
i_s, I_s = instantaneous and peak values of a-c source current
K_1, K_2 = specific values for A and B respectively
L_0 = unsaturated coil inductance
L_i = differential coil inductance, at coil current i
m = symbol for ratio $3a_3/4a_1$
N = number of turns on each load coil
P_1, P_2 = operating points, defined by intersection of ψ_1 and ψ_2
R = resistance of each of two branch circuits
S = symbol for term $(\omega^2/\omega_0^2)-1$
t = time variable
Z_2 = unsaturated impedance of branch carrying smaller of two branch currents
$\approx$ = symbol denoting an approximate equality
$\triangleq$ = symbol denoting a definition
α, β = co-ordinates resulting from transformation of A,B co-ordinates
δ = phase angle between e_s and the time derivative of e_0
Δ = switching ratio, $=I_1/I_2$
ω_0 = unsaturated resonant angular frequency of either branch
ω = angular frequency of source
θ = phase angle between I_1 and I_2
φ_1 = instantaneous flux in the core of the coil carrying larger of two branch currents
φ_2 = instantaneous flux in core of coil carrying smaller of two branch currents
ψ_1 = symbol designating operating ellipse
ψ_2 = symbol designating intersecting curve
ψ_3 = symbol designating limiting hyperbola

In using the final design equations, it

must be carefully recognized that all expressions for voltages and currents in terms of the circuit parameters are given as peak values and not as effective or rms values.

Section I. Limiting Parameter Values

Consider the system shown in Fig. 2. If this circuit is to be bistable, certain necessary relations will need to exist between the parameters. In this section some of these basic relations are explored considering the system to be loss-free.

Since the two coils are identical, and since the flux-current relationship is assumed to be nonlinear, it follows that, ignoring all hysteresis effects, the currents can be related to their respective core fluxes by power series with identical coefficients. However, inasmuch as the calculations become staggeringly complicated with the use of terms of higher order, and in view of the quesionable engineering value of the increased accuracy resulting from the use of higher-order terms, the following calculations will not consider terms beyond the third power. Thus, the following relations are assumed

$$i_1 = a_1\varphi_1 + a_3\varphi_1^3 \qquad i_2 = a_1\varphi_2 + a_3\varphi_2^3 \tag{1}$$

where i_1 and i_2 are the branch currents, φ_1 and φ_2 are the corresponding fluxes, and a_1 and a_3 are constants defined by the core material, the core geometry, and the number of turns on each core.

Little is gained in a practical circuit, with the introduction of even the fifth-power term, which case has been treated in some detail by this author, but is here omitted to conserve space.[11,12]

Two equations can be written for the circuit

$$i_s = i_1 + i_2 \tag{2}$$

$$e_0 = N\dot{\varphi}_1 + \frac{1}{C_2}\int i_1 dt = N\dot{\varphi}_2 + \frac{1}{C_2}\int i_2 dt \tag{3}$$

where i_s = source current, e_0 = branch voltage, N = number of turns on each core, and C_2 = value of the series capacitor of each of the two branches.

In the calculations which follow, only the fundamental components of fluxes and currents are considered. This, too, is an approximation, of course. To justify the phase of the fundamental component of flux, in the vector diagram of Fig. 5, the following considerations may be helpful: The branch parameters are assumed to be such that the branch with the smaller current is unsaturated and hence highly inductive, and the branch with the larger current, though highly saturated, still remains predominantly inductive. That the phase relations of the various vectors derived from these assumptions are approximately correct is demonstrated by reference to the oscillograms of an actual circuit; see Fig. 3, for example. The two core fluxes are thus found to lead the source voltage by 90 degrees, as shown in Fig. 5, and hence

$$\varphi_1 = A \cos \omega t \qquad \varphi_2 = B \cos \omega t \tag{4}$$

where A and B are the amplitudes of the fundamental components of core fluxes and ω is the angular frequency of the a-c source.

These latter expressions are substituted into equations 2 and 3, with the aid of the trigonometric identity given in Appendix I, equation 70 resulting in

$$I_s = a_1(A+B) + \left(\frac{3}{4}\right)a_3(A^3+B^3) \tag{5}$$

$$0 = (A-B)\left(\frac{a_1}{C_2} - \omega^2 N\right) + \left(\frac{3a_3}{4C_2}\right)(A^3-B^3) \tag{6}$$

For any one given value of I_s there is therefore at least one value each for the amplitudes of the two core fluxes A and B, resulting from the simultaneous solution of the two cubic equations 5 and 6. Moreover, because of the complete symmetry of these equations with regard to A and B, there exists in addition to each set of values

$A = K_1 \qquad B = K_2$

another set of values

$A = K_2 \qquad B = K_1$

The basic condition of bistability is hereby established, if it may be assumed without proof that all other states are unstable. (Whether the limiting conditions here derived are necessary and sufficient to ensure the instability of all other operating points has not been determined thus far. In fact, subsequent analysis shows the existence of other possible pairs of stable operating points under certain conditions. They can be removed by proper design, however, and are here ignored.) Of course, it may happen that the expressions for A and B in terms of the system parameters do not result in real numbers, in a given case, and it is the purpose of this section to establish the limiting conditions, for which two of the solutions to equation 5 and 6 are not real.

In addition to these two sets of core fluxes, there evidently exists a further solution: $A = B$. Its value is determined by solving the following cubic equation for A, which results from equation 5.

$$I_s = 2a_1A + \left(\frac{3a_3}{2}\right)A^3 \tag{7}$$

Inasmuch as the condition $A = B$ does not represent bistability, it may be considered trivial. Physically, it represents the labile equilibrium condition of the bi-

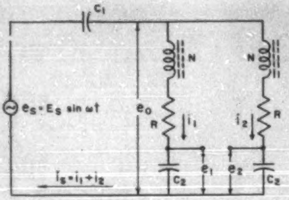

Fig. 4. Schematic diagram of the low-loss ferroresonant trigger pair

stable system, and is therefore of philosophic interest only.

If the case $A=B$ is excluded, in equation 6, the following relation remains

$$0=\left(\frac{a_1}{C_2}-\omega^2 N\right)+\left(\frac{3a_3}{4C_2}\right)(A^2+AB+B^2) \quad (8)$$

It now becomes convenient to introduce some new definitions of terms. Thus

$$L_0=N\frac{d\varphi}{di}\bigg]_{i=0,\ \phi=0}$$

In recognition of equation 1, $i=0$, $\varphi=0$, this expression for the unsaturated inductance of the inductor becomes

$$L_0=\frac{N}{a_1} \quad (9)$$

Further, L_0 and C_2 define a frequency

$$\omega_0^2 \triangleq \frac{1}{L_0C_2}=\frac{a_1}{NC_2} \qquad \frac{NC_2}{a_1}=\frac{1}{\omega_0^2} \quad (10)$$

The factor $3a_3/4a_1$ will recur often and for many manipulations it is conveniently expressed as

$$m \triangleq \frac{3a_3}{4a_1} \quad (11)$$

With the aid of equations 10 and 11, equations 5 and 6 will respectively read as follows if the trivial case $A=B$ is excluded

$$\psi_1 \equiv 0=-\frac{I_s}{a_1}+(A+B)+m(A^2+B^2) \quad (12)$$

$$\psi_2 \equiv 0=-S+m(A^2+AB+B^2) \quad (13)$$

where S is given by

$$S \triangleq \left(\frac{\omega^2}{\omega_0^2-1}\right)=\omega C_2\left(\omega L_0-\frac{1}{\omega C_2}\right) \quad (14)$$

Equations 12 and 13 now need to be solved simultaneously. However, methods such as the broadside attack of eliminating one of the unknowns will result in a sixth degree equation in the other unknown, and only a graphical solution is likely to succeed, with its inevitable loss of generality.

First, equation 13 will be examined more closely. Clearly, it relates all possible values of A and B, and only the introduction of equation 12 provides the additional conditions which pair possible values of A and B. The curve in the A-B plane, given by equation 13 is an ellipse, and after rotation of the axes by 45 degrees, the transformed equation becomes

$$\psi_2 \equiv 0=3\alpha^2+\beta^2-\frac{2S}{m} \quad (15)$$

Thus, the ellipse is seen to have the half-axes

$$a_\alpha=\sqrt{\frac{2S}{3m}} \qquad a_\beta=\sqrt{\frac{2S}{m}} \quad (16)$$

From equation 16 it is immediately evident that a necessary condition for realizability of bistability is

$$S>0 \text{ and hence } \omega>\omega_0 \quad (17)$$

Unfortunately, equation 12 does not suggest a quantitative graphical interpretation. However, it is the coexistence of the ellipse, ψ_2 of equation 15, and the curve ψ_1 in the A-B plane and represented by equation 12, which defines the stable operating points. This is illustrated in Fig. 6, which shows both curves.

From Fig. 6, several important conclusions may be drawn:

1. If the parameters of ψ_1 and ψ_2 are suitably chosen, there may exist four, rather than two, pairs of values of A and B. The limit of this condition occurs if the two curves have a common point at $A=B=\sqrt{S/3m}$ and points P_1 and P_2 coincide. Thus, for bistability, a condition more stringent than equation 17 will need to be met.

2. If large fluxes, and hence currents, are desired in the two branch circuits, parameter m in equation 16 should be made small. This implies, from equation 11, that only a small degree of nonlinearity is desired, in the flux-current relationship of the inductor. Conversely, if the system is to operate with small currents, a highly nonlinear core characteristic should be selected.

3. To determine the limiting values of circuit parameters for which bistability can be realized, the two curves must, in the limit, osculate at another point, besides the point $A=B$.

Next, the limiting parameter relations suggested by statements 1 and 3 ,will be determined.

If ψ_1 and ψ_2 are to osculate, the following expressions must hold

$$\frac{\partial\psi_1}{\partial A}=\frac{\partial\psi_2}{\partial A} \qquad \frac{\partial\psi_1}{\partial B}=\frac{\partial\psi_2}{\partial B} \quad (18)$$

Application of equation 18 to equations 12 and 13 results in, respectively

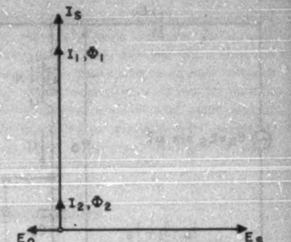

Fig. 5. Vector diagram for the loss-free ferroresonant trigger pair

$$1+3mA^2=m(2A+B) \quad (19)$$

$$1+3mB^2=m(A+2B) \quad (20)$$

Division of these two equations by each other and subsequent simplification result in a curve which relates the A-B coordinates at all points at which a common tangent can be formed

$$3m(A^2-B^2)+(6mAB-1)(A-B)=0 \quad (21)$$

Evidently the straight line $A=B$ also defines such a point, as was anticipated in the foregoing statement 1. Intersection with ψ_2 yields

$$A=B=\pm\sqrt{\frac{S}{3m}} \quad (22)$$

If the constant I_s in ψ_1 is now adjusted so as to place the point of tangency on ψ_1, there follows from equations 12 and 22

$$\boxed{|I_s|<2a_1\left(\frac{S}{3+1}\right)\sqrt{\frac{S}{3m}}} \quad (23)$$

for no more than two stable operating points. Equation 23 thus defines the limit value of I_s. If I_s exceeds this value, the point $A=B$ on ψ_1 moves further away from the origin, and there may exist four stable operating points. If it falls below this value, there will be only two stable operating points.

If the relation of the parameters is not proper, ψ_1 may not exist in the form shown in Fig. 6 and only the trivial condition $A=B$ may be realizable. This aspect will be examined next.

If the condition $A=B$ is excluded, in equation 21 the following relation results

$$\psi_3 \equiv 0=A^2+3AB+B^2-\frac{1}{3m} \quad (24)$$

This expression represents the hyperbola ψ_3 in the α-β plane in Fig. 6. Rotating the axes again by 45 degrees results in

$$\psi_3 \equiv 0 = 5\alpha^2 - \beta^2 - \frac{2}{3m} \qquad (25)$$

The half axes are given by

$$b_\alpha = \sqrt{\frac{2}{15m}} \qquad b_\beta = \sqrt{\frac{2}{3m}} \qquad (26)$$

The ellipse ψ_2 and the hyperbola ψ_3 will intersect if their respective half-axes obey the relation

$$b_\alpha < a_\alpha \text{ or } \sqrt{\frac{2}{15m}} < \sqrt{\frac{2S}{3m}} \qquad (27)$$

Thus, if such an intersection is to exist, thereby permitting a point of osculation for ψ_1 and ψ_2, the following limitation must be imposed

$$\boxed{S > 1/5 \text{ or } \omega^2 > 1.2\omega_0^2} \qquad (28)$$

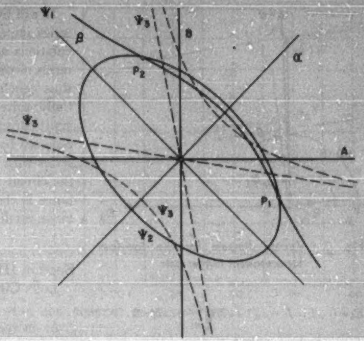

Fig. 6. Graphical representation of the three operating characteristics ψ_1, ψ_2, and ψ_3, which define the response of the ferroresonant trigger pair

Section II. Responses of Loss-Free Circuit

The preceding section dealt with the limiting relations among the circuit parameters, for which a bistable system results. In the calculations which follow, the actual values of the branch currents, output voltage, and supply voltage will be determined for the loss-free system. Again, only the first two terms of the current-flux power series will be considered. It is assumed that the circuit parameters have been so adjusted as to permit bistability.

It was demonstrated in the preceding section that the intersections of ψ_1 and ψ_2 in Fig. 6 represent the stable operating points. For their quantitative evaluation, equations 12 and 13 need to be solved simultaneously. Clearly, a general solution of these two equations is not readily available. However, under certain justifiable assumptions, successive approximations are possible. The two equations are

$$\psi_1 \equiv 0 = -\frac{I_s}{a_1} + (A+B) + m(A^3+B^3) \qquad (29)$$

$$\psi_2 \equiv 0 = -S + m(A^2+AB+B^2) \qquad (30)$$

If the system is to be of practical use, it may be stipulated that one of the stable states shall result in a negligible branch current, the other being large. Expressed otherwise, it is required that the "switching ratio" Δ be as large as possible, the latter being defined as the ratio, of the larger to the smaller current, for either of the two stable states, P_1 or P_2, in Fig. 6. Reference to the oscillograms in section III shows that adequate experimental justification is available for the following statement

$$\begin{array}{lll} B \approx 0 & A \gg 0 & \text{at } P_1 \\ B \gg 0 & A \approx 0 & \text{at } P_2 \end{array} \qquad (31)$$

It will be understood, of course, that such a desirable performance will impose certain further restrictions on the source voltage and current, which will subsequently be determined. In accordance with these statements, flux B in equation 30 is set equal zero, resulting in

$$A = \pm\sqrt{\frac{S}{m}} \qquad B = 0 \qquad (32)$$

If a better approximation is desired, the following procedure may be followed: First, equation 40 is multiplied again, by $(A\text{-}B)$; then equation 29 is equated to the result. After simplification, the following relation is found

$$B = \frac{\left[\left(\frac{I_s}{a_1}\right) + A(S-1) - 2mA^3\right]}{(S+1)} \qquad (33)$$

This value of B could now be introduced into equation 30, and a new, improved value of A be found. This new value, upon substituting into equation 33, will yield a corrected value for B. Thus, by successive approximation, good accuracy can be achieved, provided the solution converges. However, in the light of the rather sweeping assumptions delineated at the beginning of the paper, it would appear that such improvements do not justify the time required to obtain them.

A check on a previous result can now be obtained: If $A = B$ in equation 30, there results, by solving equation 30 for A

$$A = \pm\sqrt{\frac{S}{3m}} \qquad (34)$$

If this value is introduced into equation 29, there follows

$$\pm I_s = 2a_1 \; 1 + \frac{S}{3}\sqrt{\frac{S}{3m}} \qquad (35)$$

Comparison with equation 23 shows this result to be identical with that obtained previously, by a different approach. Thus, to ensure bistability, the source current must not exceed the value given in equation 35. This permits the establishment of a relation between source voltage and branch voltage

$$E_0 + E_s = I_s\left(\frac{1}{\omega C_1}\right) \qquad (36)$$

Hence, for bistability

$$E_s < \left(\frac{2a_1}{\omega C}\right) 1 + \frac{S}{3}\sqrt{\frac{S}{3m}} - E_0 \qquad (37)$$

The desirability of the largest possible switching ratio has been decided upon; it now remains to determine the conditions which permit this ratio to become infinite. Thus, if $B = 0$, the following must hold

$$E_0 = 0 \quad I_1 = I_s \quad I_2 = 0 \quad E_s = \frac{I_s}{\omega C_1} \quad E_1 = \frac{I_s}{\omega C_2} \quad E_2 = 0 \qquad (38)$$

Of interest is the observation that in the vicinity of optimum operation, the smaller of the two branch currents may be made to reverse phase, as I_s varies slightly. Thus, points P_1 and P_2 of Fig. 6 may both fall into the first quadrant of the A-B plane, or else P_2 and P_1 are in the second and fourth quadrants respectively.

Since current and flux are related by

$$i_1 = a_1\varphi_1 + a_3\varphi_1^3 \qquad (39)$$

there follows, for the case $\varphi_1 = A\cos\omega t$, $\varphi_2 = 0$, that the nonzero branch current is as follows

$$I_1 = a_1A + \frac{3a_3A^3}{4} \qquad (40)$$

Then, in recognition of equations 34 and 40, the following relations result by substitution into equations 35 to 38, i.e., for the optimum case.

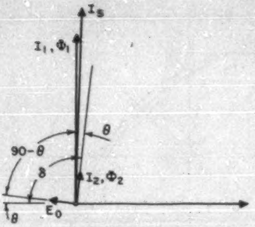

Fig. 7. Vector diagram for the low-loss ferroresonant trigger pair

$$E_0=0 \quad I_1=I_s=a_1(1+S)\sqrt{\frac{S}{m}} \qquad I_2=0$$

$$E_1=\left[\frac{a_1(1+S)}{\omega C_2}\right]\sqrt{\frac{S}{m}}=\left(\frac{a_1\omega}{\omega_0{}^2C_2}\right)\sqrt{\frac{S}{m}}$$

$$=\omega N\sqrt{\frac{S}{m}} \qquad E_2=0 \quad (41)$$

$$E_s=\left[\frac{a_1(1+S)}{\omega C_1}\right]\sqrt{\frac{S}{m}}=\left(\frac{a_1\omega}{\omega_0{}^2C_1}\right)\sqrt{\frac{S}{m}}$$

$$=\omega N\left(\frac{C_2}{C_1}\right)\sqrt{\frac{S}{m}}$$

It can thus be seen that supply voltage and output voltage in the optimum case are related by the equation

$$E_1=E_s\left(\frac{C_1}{C_2}\right) \qquad (42)$$

It is evidently advantageous to make the capacitance ratio C_1/C_2 as large as possible, still remaining, of course, in accordance with equation 36 to 38.

It is quite likely, that a design in accordance with equation 41 will require rather large source voltages, and a compromise between optimum and realistic design may be necessary. In this case the branch voltage will not be zero, and the lower of the branch currents is given to a sufficient approximation by

$$I_2=\frac{E_0}{\left(\omega L_0-\frac{1}{\omega C_2}\right)}=E_0\left(\frac{\omega C_2}{S}\right) \qquad (43)$$

Since the switching ratio can be defined as

$$\Delta \triangleq \frac{I_1}{I_2}=\frac{(I_s-I_2)}{I_2}=\left(\frac{I_s}{I_2}\right)-1 \qquad (44)$$

and since, approximately

$$I_s=\frac{(E_s+E_0)}{\omega C_1} \qquad I_2=E_0\left(\frac{\omega C_2}{S}\right) \qquad (45)$$

there follows, by substituting equation 45 into equation 44

$$\boxed{\Delta=\left(\frac{C_1}{C_2}\right)S\left(\frac{1+E_s}{E_0}\right)-1} \qquad (46)$$

It will be noted that the nature of the series impedance does not enter the calculations as long as all responses are in terms of the source current I_s. One may thus conclude that the circuit is essentially suited to be driven from a constant-current source, but the latter can be replaced by a constant-voltage supply in series with any arbitrary impedance. In the circuit under consideration, a capacitance is chosen, but resistance or inductance would also serve the purpose.

Section III. Responses of Low-Loss Circuit

As in section I, the current-flux relations are assumed to be simply

$$i_1=a_1\varphi_1+a_3\varphi_1{}^3 \qquad i_2=a_1\varphi_2+a_3\varphi_2{}^3 \qquad (47)$$

Corresponding to equations 2 and 3, two relations can be established for the circuit of Fig. 4

$$i_s=i_1+i_2 \qquad (48)$$

$$e_0=N\dot{\varphi}_1+Ri_1+\left(\frac{1}{C_2}\right)\int i_1dt$$

$$=N\dot{\varphi}_2+Ri_2+\left(\frac{1}{C_2}\right)\int i_2dt \quad (49)$$

After differentiation and application of equation 47, equation 49 reads

$$N(\ddot{\varphi}_1-\ddot{\varphi}_2)+Ra_1(\dot{\varphi}_1-\dot{\varphi}_2)+$$
$$3Ra_3(\varphi_1{}^2\dot{\varphi}_1-\varphi_2{}^2\dot{\varphi}_2)+$$
$$(\varphi_1-\varphi_2)\frac{a_1}{C_2}+\left(\frac{a_3}{C_2}\right)(\varphi_1{}^3-\varphi_2{}^3) \quad (50)$$

The next consideration concerns the assumption of a phase for the fundamental components of currents of the two branches, and hence for the two core fluxes. However, once again the calculations will become rather involved, unless certain simplifying assumptions are made. Thus, one may require that the series capacitor be so chosen that

$$\frac{I_s}{\omega C_1}\gg E_0 \qquad (51)$$

This condition is normally met, since E_0 is nearly always negligibly small; I_s is then determined primarily by the reactance of C_1, and leads the source voltage by approximately 90 degrees.

Furthermore, in a practical design the switching ratio should be at least five, so that the larger of the two branch currents is approximately in phase with the source current. As outlined in section I, both branches may still be assumed to be predominantly inductive. This is clearly shown in the oscillograms of Fig. 3, where the fundamental components of the branch currents may be said to lead the source voltage by about 90 degrees and are approximately in phase with each other. Thus, a vector diagram for the low-loss case would appear as shown in Fig. 7.

Fig. 3 shows two complete sets of oscillograms, for an actual circuit. Fig. 3 (A) shows the response for $E_s=100$ volts rms and Fig. 3(B) for $E_s=250$ volts rms, for comparison.

Based upon the preceding evidence, the following assumptions of flux wave equations are reasonably justified, for one of the two stable states

$$\varphi_1=A\cos\omega t \qquad \varphi_2=B\cos(\omega t-\theta) \qquad (52)$$

The phase angle between these two fluxes can be determined as shown in Appendix II, and is given by the equation

$$\theta=\left[\tan^{-1}\frac{(S-mB^2)}{R\omega C_2(1+mB^2)}\right]-90° \qquad (53)$$

It is interesting to note that θ will decrease as B is increased. Thus, a larger source voltage will decrease the phase angle between the two fluxes. This observation is also illustrated by the oscillograms of Fig. 3(A) and (B), if the fluxes may be assumed to be in phase with their respective magnetomotive forces.

The assumption is now made that the circuit should have reasonably low losses, so that θ is a very small angle but not zero. Moreover, the quantity mB^2 in equation 53 shall be small compared to S, and compared to unity. Justifications for these assumptions are found in Appendix II, where their introduction is shown to lead to the following value, for the critical resistance of bistability.

$$\boxed{\begin{array}{l} R<\sqrt{\left(\omega L_0-\frac{1}{\omega C_2}\right)\left(\frac{1}{\omega C_2}\right)} \\ \text{or}\sqrt{\frac{S}{\omega C_2R>1}} \end{array}} \qquad (54)$$

The qualitative implication of equation 54 is important; the closer the operating frequency approaches the natural frequency of each branch in the unsaturated state, the lower the resistance must be kept, to permit bistability.

A rough approximation of the larger of the two core fluxes is now obtained from equation 87 by assuming B^2 and AB to be negligible, compared to A^2, thus

$$A\approx\pm\sqrt{\frac{(S^2+R^2\omega^2C_2{}^2)}{m(S-R^2\omega^2C_2{}^2)}} \qquad (55)$$

The source current, and hence the larger of the two branch currents, is given by a calculation similar to equation 36 to equation 41, resulting in

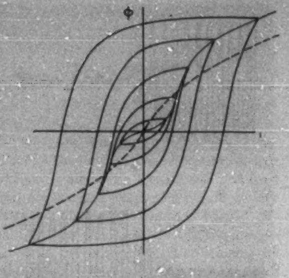

Fig. 8. Nest of hysteresis loops. The loop tips are connected by the magnetization line, of which the broken curve is a useful approximation

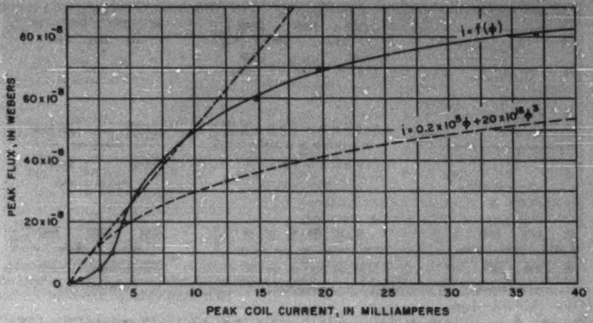

Fig. 9. Experimentally obtained magnetization line I=f(φ), and its 2-term approximation. The two curves have similar slopes, in certain ranges

$$I_s \approx I_1 = a_1(S+1)\sqrt{\frac{(S^2+R^2\omega^2C_2^2)}{m(S-R^2\omega^2C_2^2)}} \qquad (56)$$

The output voltage is found from

$$E_2 = \frac{I_s}{\omega C_2} \qquad (57)$$

where I_s is given by equation 56.

In this evaluation of the source current, it was found desirable to assume both the branch voltage, and the smaller branch current to be zero. A better approximation of the branch voltage, and subsequently of the smaller branch current, can be obtained as follows: from equation 49, after substitution of equation 47 and differentiation, the following relation results for the fundamental components only

$$E_0^2 = \left(\frac{a_1^2}{\omega^2C_2^2}\right)[(-SA+mA^3)^2+ R^2\omega^2C_2^2(A+mA^3)^2] \qquad (58)$$

The approximate value for A given in equation 55 can now be substituted into equation 58, resulting in

$$E_0 = \frac{a_1R(S+1)(S^2+R^2\omega^2C_2^2)}{(S-\omega^2R^2C_2^2)\sqrt{m(S-R^2\omega^2C_2^2)}} \qquad (59)$$

Since the core carrying flux φ_2 is essentially unsaturated, its branch impedance is quite accurately given as

$$Z_2 = \sqrt{R^2+\left(\omega L_0-\frac{1}{\omega C_2}\right)^2} \equiv \left(\frac{1}{\omega C_2}\right)\sqrt{R^2\omega^2C_2^2+S^2} \qquad (60)$$

Thus, the smaller branch current is found from equation 51 and equation 60 as

$$I_2 = \frac{E_0}{Z_2} = \left[\frac{a_1R\omega C_2(S+1)}{(S-R^2\omega^2C_2^2)}\right] \sqrt{\frac{(S^2+R^2\omega^2C_2^2)}{m(S-R^2\omega^2C_2^2)}} \qquad (61)$$

For small resistance, this reduces to

$$I_2 \approx \frac{a_1R\omega C_2(S+1)}{\sqrt{mS}} \qquad (62)$$

The switching ratio is now readily determined, from equations 56 and 61

$$\Delta = \frac{(S-R^2\omega^2C_2^2)}{\omega RC_2} \qquad (63)$$

If the resistance is sensibly small, the second term in the numerator can be neglected with respect to the first term, resulting in

$$\Delta \approx \frac{S}{\omega RC_2} \equiv \sqrt{S}\left(\frac{\sqrt{S}}{\omega RC_2}\right) \qquad (64)$$

Equation 64 shows why a small resistance is most desirable, where large switching ratios are needed.

It is also interesting to note that the switching ratio as here defined, is not a function of the degree of nonlinearity. However, as can be seen from equation 56 and equation 62, both branch currents increase, as m is decreased. Thus, a slightly nonlinear system will carry the larger branch currents, and hence develop higher output voltages, whereas the highly nonlinear system will have small currents, and lower voltages, with the same switching ratio for both systems, as long as the systems are identical with regard to all small-signal parameters.

Section IV. Experimental Results

It is the purpose of this section to state such experimental evidence as has been accumulated pertaining to the ferroresonant flip-flop, regardless of the support or the contradiction which this evidence may offer of the theoretical developments derived in the preceding sections. Also, since the calculations are concerned only with the fundamental components of voltage and currents, a comparison with test data becomes in several instances, a matter of interpretation. Clearly, various further tests (as well as improved experimental techniques, notably the use of a narrow-band filter to select for measurement the fundamental components, and to reject all harmonics) would have been helpful. Alternately, a Fourier analysis of all the complex wave shapes could have been carried out. If, however, this omission remains the major flaw in the developments outlined in the analysis, the author will cheerfully yield this point to the critic.

The following describes the nonlinear inductors used in the experimental setup:

Core material by Syracuse General Electric Company, no. 2.98 and 2.99.

Shape of core: Toroid with rectangular cross section.

Approximate size: Inside diameter: 0.275 inch; outside diameter: 0.39 inch; thickness: 0.07 inch.

Power winding: 50 random-wound turns of four strands of Formex-insulated wire, size 26. The resultant four coils are connected in additive series, forming a 200-turn coil, self-resonant at about 500 kc.

Trigger coil: 100 random-wound turns of Formex-insulated wire, size 36, on a 9/16-inch circular coil form, surrounding the toroid. Axis of trigger coil and axis of toroid are at right angles to each other. The trigger coils of the two branches are series-connected and supplied with trigger pulses.

The first step in the performance prediction of the ferroresonant trigger pair is, of course, the determination of the coefficients of the current-flux relation of equation 47. Several methods are outlined in Appendix III, and it is sug-

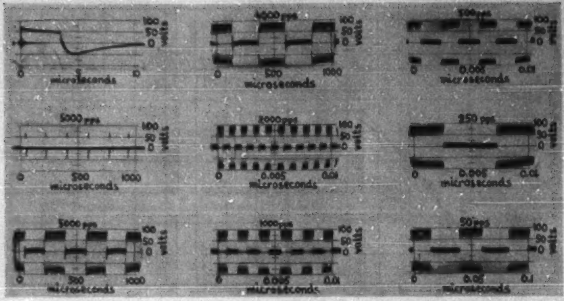

Fig. 10. Response of the ferroresonant trigger pair to 3.5-microsecond 65-volt trigger pulses, at trigger rates ranging from 5,000 to 50 pulses per second. $E_s = 50$ volts; $f = 233$ kc

gested there that a dynamic measurement would yield more reliable data. Accordingly, one of the two identical cores with 200 turns each was connected in series with a 10-ohm resistor and an adjustable voltage source of 233 kc, and of sinusoidal wave shape. The peak value of flux in the core for any given value of source voltage is given, to a sufficient approximation, by the relation

$$\varphi_{\text{peak}} = E_{\text{rms}} \frac{10^8}{4.44fN} = 0.483E_{\text{rms}} \qquad (65)$$

The peak value of exciting current corresponding to any one value of source voltage is proportional to the voltage drop across the 10-ohm resistor in series with the coil, and a plot of peak flux versus peak current thus obtained yields a "magnetization line" which connects the tips of a nest of hysteresis loops, as shown in Fig. 8. The result of this procedure is shown in Fig. 9.

It is readily seen from Fig. 9 that a satisfactory 2-term approximation is not possible, if the actual current-flux relation is to be simulated over a sufficiently wide range.

The reader can convince himself readily that very widely different choices of the two coefficients of equation 65 are possible all of which appear to have merits over certain ranges. Indeed, an improvement is sometimes possible by allowing the first coefficient to become negative, which implies a negative value of inductance for very small currents, and a physical justification of such a term becomes rather tenuous. Once more, then, it appears wise to take stock of the physics of the device before proceeding with the mathematics.

The significant circuit parameter is the rate at which flux varies with current; this quantity is, of course, related to the differential inductance by the number of turns, as seen from equation 66, and it is this same differential inductance which governs the manner in which the instantaneous current through the coil varies with the voltage across the coil.

$$e_{L_1} = N\frac{d\varphi}{dt} = N\left(\frac{d\varphi}{di}\right)\left(\frac{di}{dt}\right) = L_1\frac{di}{dt} \qquad (66)$$

Thus, an approximation appears indicated in which the slopes near the origin and over a wide part of the saturation range approximate their respective experimental equivalents. Such an approximation is shown in Fig. 9, and is governed by the relation.

$$i = 0.2\times10^5\varphi + 20\times10^{15}\varphi^3 \qquad (67)$$

It is now obvious why, in the author's opinion, an enhancement of mathematical accuracy through choice of a third term in the current flux relation, becomes meaningless.

The coil resistance is negligible and, from this choice of the coefficients a_1 and a_3, the following data are obtained (for $N = 200$, $f = 233$ kc, and $C_1 = C_2 = 500 \times 10^{-12}F$)

$$\omega_0^2 = \frac{a_1}{NC_2} = 0.2\times10^{12} \qquad \omega = 1.46\times10^6$$

$$\omega^2 = 2.14\times10^{12}$$

$$S = \left(\frac{\omega^2}{\omega_0^2} - 1\right) = 9.7 \qquad m = \frac{3a_3}{4a_1} = 7.5\times10^{11}$$

$$\sqrt{\frac{S}{m}} = 1.16\times10^{-6} \qquad (68)$$

For the optimum case the following results were obtained

$$E_0 = 0 \quad E_s = \left(\frac{\omega NC_2}{C_1}\right)\sqrt{\frac{S}{m}} = 333 \text{ volts peak}$$

$$E_1 = \omega N\sqrt{\frac{S}{m}} = 333 \text{ volts peak} \quad E_2 = 0 \qquad (69)$$

$$I_1 = I_s = a_1(1+S)\sqrt{\frac{S}{3m}} = 0.14\text{-ampere}$$

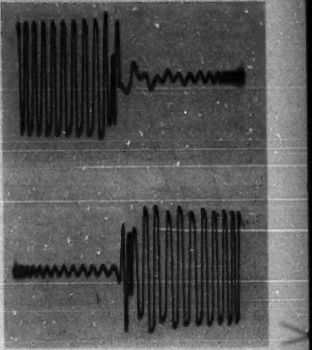

Fig. 11. State changes of the ferroresonant trigger pair. Approximately 5 cycles are needed to change from the high-current state to the low-current state, or vice versa

$$\text{peak} \qquad I_2 = 0 \qquad \Delta = \frac{I_1}{I_2} = \infty$$

The source voltage dictated by optimum considerations is rather large, resulting in large currents and excessive core heating. However, comparable results are obtainable with smaller source voltages. Oscillograms for two such cases were shown in Fig. 8, and approximate numerical results are listed in Table I. (It should be noted once more that a Fourier analysis of the curves of Fig. 3(A) and (B) is needed to obtain the exact peak values of the fundamental components of voltages and currents.)

The switching ratios resulting from the two source voltages listed in Table I are calculated from the ratio of the fundamental components of branch currents or, if preferred, from the ratios of the fundamental components of output voltages. They can also be calculated as follows

Source voltage E_s, volts peak	100	250
Calculated $\Delta = \left(\frac{1+E_0}{E_0}\right)\frac{SC_1}{C_2}$	28.1	44
Measured Δ	20	31

The response of the ferroresonant trigger pair to various trigger pulse rates is shown in Fig. 10. Due to pulse rate limitations on the equipment supplying the trigger signals, the limit on circuit response could not be determined readily. However, as seen from the oscillograms of Fig. 11, approximately five cycles of the carrier frequency are needed for a change of state of the circuit. Thus, for the circuit tested, the ultimate trigger rate may be expected to be of the order: trigger rate = 1/5 (frequency).

It is interesting to note that the use of a trigger circuit of low impedance lowers the source voltage necessary for bistability. This is readily understood, however, from an inspection of equation 41. Clearly, the smaller the quantity S becomes, the lower the necessary source voltage. Since the trigger coil and load coil are coupled magnetically, albeit only slightly, the low-impedance trigger circuit has the effect of reducing the inductance of the power coil, thus raising its unsaturated resonant frequency. Since this results in a reduction of S, the reduction of source voltage observed in taking the data of Figs. 10 and 11 appears satisfactorily explained.

Appendix I

The following three trigonometric identities have been used in the preceding analysis

$$(\cos x)^{2n+1} \equiv (1/2^{2n})[\cos(2n+1)x + (2n+1)\cos(2n-1)x + \binom{2n+1}{2}\times \cos(2n-3)x + \binom{2n+1}{3}\times \cos(2n-5)x + \ldots\binom{2n+1}{k-1}\times \cos(2n-2k+3)x\ldots] \quad (70)$$

$$\sin x \cos^2 x \equiv (1/4)\sin x + (1/4)\sin 3x \quad (71)$$

$$\cos(\omega t-\theta) \equiv \cos\omega t \sin\theta + \sin\omega t \cos\theta \quad (72)$$

$$\sin(\omega t-\theta) \equiv \sin\omega t \cos\theta - \cos\omega t \sin\theta$$

Appendix II

The angle θ can be determined from equation 47, as the phase angle relating the in-phase and quadrature components of φ_2 as follows

$$\dot{e}_0 = \left(N\ddot{\varphi}_2 + \frac{i_2}{C_2}\right) + R\dot{i}_2 \quad (73)$$

If the current-flux relation of equation 47 is introduced, there results:

$$\dot{e}_0 = \left[N\ddot{\varphi}_2 + \frac{(a_1\varphi_2 + a_3\varphi_2^3)}{C_2}\right] + [Ra_1\dot{\varphi}_2 + 3Ra_3\varphi_2^2\dot{\varphi}_2] \quad (74)$$

This equation converts to the following, with the aid of trigonometric identities of equations 70 and 71, Appendix I, provided only the fundamental components are related, as

$$\dot{e}_0 = \left[\left(-N\omega^2 + \frac{a_1}{C_2}\right)B + \frac{3a_3B^3}{4C_2}\right]\cos(\omega t-\theta) - R\omega\left(a_1B + \frac{3a_3B^3}{4}\right)\sin(\omega t-\theta) \quad (75)$$

With the introduction of the terms

$$\omega_0^2 \triangleq \frac{a_1}{NC_2} \qquad m \triangleq \frac{3a_3}{4a_1} \qquad S \triangleq \left(\frac{\omega^2}{\omega_0^2} - 1\right) \quad (76)$$

the phase of $\dot{e}_0$ is thus given by

$$\tan\delta = (S - mB^2)/R\omega C_2(1+mB^2) = \left[\frac{\left(\frac{\omega^2}{\omega_0^2}\right)}{R\omega C_2(1+mB^2)}\right] - \frac{1}{R\omega C_2} \quad (77)$$

The angle can now be found from

$$\theta = \left[\tan^{-1}\frac{(S-mB^2)}{R\omega C_2(1+mB^2)}\right] - 90° \quad (78)$$

Since the two branches are in parallel, the two branch voltages must be identical, and the following equality must hold

$$(-SB+mB^3)\cos(\omega t-\theta) - R\omega C_2(B+mB^3)\sin(\omega t-\theta) = (-SA+mA^3)\cos\omega t - R\omega C_2(A+mA^3)\sin\omega t \quad (79)$$

With the use of the trigonometric identities 72 in Appendix I, this latter equation can be expanded, and two independent relations result from equating the sine and cosine expressions, respectively:

$$(-SB+mB^3)\cos\theta + R\omega C_2(B+mB^3)\sin\theta = (-SA+mA^3) \quad (80)$$

$$(-SB+mB^3)\sin\theta - R\omega C_2(B+mB^3)\cos\theta = -R\omega C_2(A+mA^3) \quad (81)$$

In recognition of the assumption of a low-loss circuit, and the evidence presented in the oscillograms, the angle θ is nearly zero degrees, and hence:

$$\cos\theta \approx 1 \quad (82)$$

Thus, equations 80 and 81 can be simplified:

$$-S(A-B) + m(A^3-B^3) = R\omega C_2B(1+mB^2)\sin\theta \quad (83)$$

$$R\omega C_2(A-B) + R\omega C_2m(A^3-B^3) = -B(-S+mB^2)\sin\theta \quad (84)$$

Dividing these two equations by each other results in:

$$[-S+m(A^2+AB+B^2)]/R\omega C_2[1+m(A^2+AB+B^2)] = -R\omega C_2(1+mB^2)/(mB^2-S) \quad (85)$$

Equation 85 reduces considerably through the assumption that: $mB^2 \ll 1$

This is not unreasonable: Equation 47 can be rewritten, for the case of cosinusoidal flux, and considering fundamental components only:

$$i_2 = Ba_1(1+mB^2) \quad (86)$$

Thus, since i_2 is assumed to be the smaller of the two branch currents, the corresponding core can be considered as linear, the second term can be neglected in comparison to the first, and $mB^2 \ll 1$ is justified. A further assumption is only conditionally permissible: It is desirable that: $mB^2 \ll S$. Here a severe error is introduced if the unsaturated natural frequency of each branch is very nearly equal to the source frequency. However, again in most practical cases, the factor S will probably exceed ten per cent whereas, for the unsaturated condition where B is small, $mB^2 \ll 0.01$, in all likelihood.

Table I. Approximations from Fig. 8

Volts Peak				Amperes Peak			
E_s	E_0	E_1	E_2	I_1	I_2	I_s	Δ
			Case 1				
100	50	80	4	0.10	0.004	0.10	20
			Case 2				
250	70	180	6	0.14	0.0045	0.13	31

After these simplifications, equation 85 is now solved for (A^2+AB+B^2):

$$A^2+AB+B^2 = (S^2+R^2\omega^2C_2^2)/m(S-R^2\omega^2C_2^2) \quad (87)$$

Clearly, this expression reduces to equation 30, for the loss-free circuit:

$$A^2+AB+B^2 = S/m \quad (88)$$

The elliptic locus given by equation 87 ceases to exist if the term on the right side becomes negative. Thus, one may establish the following limitation on the resistance, if bistability is to exist:

$$R < \left(\frac{1}{\omega C_2}\right)\sqrt{\left(\frac{\omega^2}{\omega_0^2} - 1\right)}$$

Rewritten this expression states:

$$R < \sqrt{\left(\omega L_0 - \frac{1}{\omega C_2}\right)\left(\frac{1}{\omega C_2}\right)} \quad \text{or} \quad \frac{\sqrt{S}}{\omega C_2 R} > 1 \quad (89)$$

Appendix III. Some Aids in Determination of Nonlinearity Constants

By supposition, the current-flux relation was given as

$$i = a_1\varphi + a_3\varphi^3 \equiv \varphi(a_1 + a_3\varphi^2) \quad (90)$$

For any given current i the differential inductance is given by $L_i \triangleq \frac{Nd\varphi}{di}$

Thus, it follows from equation 90 that

$$L_i = \frac{N}{a_1} + a_3\varphi^2 \quad (91)$$

Thus, the initial inductance is given by

$$L_0 = \left(N\frac{d\varphi}{di}\right)\bigg]_{i=0} = \frac{N}{a_1} \quad (92)$$

and hence the linearity coefficient becomes

$$a_1 = \frac{N}{L_0} \quad (93)$$

If equaton 93 is substituted into equation 91, and the result is solved for the flux, there follows

$$\varphi = \sqrt{\left(\frac{N}{3a_3}\right)\left[\left(\frac{1}{L_i}\right) - \left(\frac{1}{L_0}\right)\right]} \quad (94)$$

Substitutions of equations 93 and 94 into equation 90 and solving for the nonlinearity coefficient, results in

$$a_3=\left(\frac{N^3}{27i^3}\right)\left[\left(\frac{1}{L_i}\right)-\left(\frac{1}{L_0}\right)\right]\times \left[\left(\frac{1}{L_i}\right)+\left(\frac{2}{L_0}\right)\right]^2 \tag{95}$$

Since the curve of L_i versus i is in general obtained by measurement, the closeness of the fit of the curve given by equation 90 and the coefficients of equations 93 and 95, can be gauged by plotting the current-inductance relation obtained through the use of the coefficients. This information is contained in equation 95 and results in the following

$$i=\left(\frac{N}{3}\right)\left[\left(\frac{1}{L_i}\right)+\left(\frac{2}{L_0}\right)\right]\times \sqrt{\left(\frac{N}{3a_3}\right)\left[\left(\frac{1}{L_i}\right)-\left(\frac{1}{L_0}\right)\right]} \tag{96}$$

A much simpler and more direct method for determining the current-flux coefficients, than the bridge method for determining inductance is based on the availability of calibrated hysteresis loop equipment. Thus, if a "nest" of hysteresis loops is taken, for either of the two identical cores, the loop tips can be connected by the magnetization line. Although the low magnetomotive force portion of this curve often deviates considerably from the relation assumed in equation 90, an approximation as shown in Fig. 9 is not unreasonable. However, an alternate simple method for obtaining the magnetization line is stated at the beginning of section IV.

Once the approximation magnetization line is determined, the desired coefficients are readily found. Thus, as in equation 92

$$\frac{1}{a_1}=\left(\frac{d\varphi}{di}\right)\Big]_{\varphi=0} \tag{97}$$

With a_1 determined, a point near the knee of the magnetization line yields the necessary data to solve for the nonlinearity coefficient a_3. Alternately, two points may be chosen on the magnetization line, resulting in two simultaneous equations

$$\begin{pmatrix}\varphi_a & \varphi_a^3\\ \varphi_b & \varphi_b^3\end{pmatrix}\begin{pmatrix}a_1\\ a_3\end{pmatrix}=\begin{pmatrix}i_a\\ i_b\end{pmatrix} \tag{98}$$

It is obvious that the hysteresis loop method yields more reliable results than that based on the curve of differential inductance versus current; the loops can, and generally should, be taken at the operating frequency of the flip-flop, and thus they very nearly represent actual dynamic operating conditions. In contrast, the differential inductance is essentially based on a d-c hysteresis loop and, as mentioned earlier, the resulting error can be severe. The unwary experimenter should be cautioned, however, that the hysteresis loop equipment should have a bandwidth of no less than 20 times the operating frequency along the magnetomotive force axis with the relative phase shift between the flux axis and the magnetomotive force axis being negligible, over this bandwidth. If these precautions are not observed, the hysteresigram may be considerably distorted. This effect is particularly noticeable in the case of core materials with pronounced nonlinearities.

Transmission of Business Machine Data Over Standard Telegraph Channels

F. B. BRAMHALL
FELLOW AIEE

Computer Requirements

THE transmission of digital information over long distances for the operation of business machines is a problem that will engage increasing attention of communication engineers. High-speed electronic computer-type business machines are being called upon more and more to operate on information fed from distant points. This new form of transmission results in encoded information which is not at all intelligible in the accustomed sense. Such communication is nevertheless telegraphy in every true sense of the word. The record of this new form of record communication may not be a printed page but rather a record more easily reread into the computer machine when needed. The technical problems encountered in the transportation of business-machine information from one point to another are those long familiar to the telegraph engineer.

While it may be expedient that the computer functions of the business machine be carried out at high speed, the operating speed of the communication circuits which bring information from distant associated business offices may be quite different. The reasons for this difference are varied. For instance, the computer may be serving several distant branches on a time-sharing basis. Further, a considerable part of the information fed to the computer for a given task may be unchanged from a recent previous assignment and may, therefore, have already been stored in memory devices. For instance, in payroll work, the hourly rates, the tax rates, and the like are probably unaltered, and only the hours information is brought in over the communication circuit each pay period. Likewise, in an inventory type of operation, prices are remembered by the machine, and only type numbers, quantities, and the like come over the wire. The required telegraphic speed then, instead of being in the region of hundreds of thousands of pulses (bits) per second, may well be such that it can be accommodated by a few hundred cycles of bandwidth or even by one or more conventional telegraph circuits. Fortunately, modern record communication facilities lend themselves readily to

---

Paper 56-654, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 27, 1956; made available for printing May 2, 1956.

F. B. Bramhall is with the Western Union Telegraph Company, New York, N. Y.

almost any signaling speed that ultimately may be proved most advantageous from the standpoint of the machine and the work it is required to perform. Only minor new developments in terminal equipment are required to accommodate these new business methods as they evolve, in any case.

Present Facilities

The 3-kc voice-width band is the vehicle of all present-day, long-haul telegraphy. Operated by time-division technique, with the coded data transmitted seriatim at high speed, this universal vehicle will convey many hundred information bits per second. It may well evolve that this commonly available unit of communication spectrum will come into wide use for feeding information to and delivering results from digital computer-type business machines. Another readily available communication spectrum unit is the half-band. The 3-kc bands of the Western Union Telegraph Company's entire trunk network are divided into two half-bands or subbands, as they are called. Each of these subbands has a useful spectrum range from approximately 350 to 1,625 cycles. This subband with a probable speed capability of perhaps 750 or 1,000 bits per second may prove to be a useful and economical spectrum unit for data transmission.

As used in conventional message traffic and private lease service, each subband carries nine telegraph channels. The signaling rate on these telegraph channels is 45, 57, or 75 bands (bits per second), depending on the nature of the service. Contemplating the widespread use of 100 speed (words per minute), particularly in private wire service of special classes, led to the design of the modern telegraph plant to render substantially errorfree transmission at 75 bits per second. Presently, a considerable demand for data transmission at rates materially lower than 750 bits per second is being met by the use of one or more of these standard trunk telegraph channels. The characteristics and capabilities of these channels are described in the following.

Frequency Modulation

The Western Union Telegraph Company pioneered in the development and application of frequency modulation for telegraphy. Its whole plant, comprising several million channel miles, is operated by this method. As a result, it enjoys a unique freedom from errors caused by changes in transmission equivalent on the vehicle channels and errors caused by extraneous disturbance from all sources.[1,2]

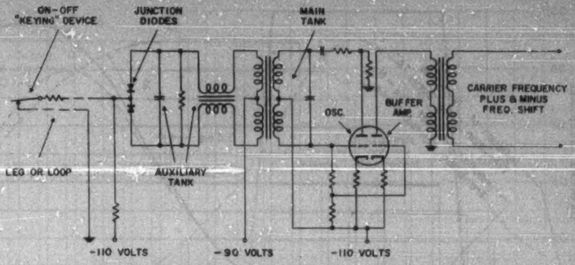

Fig. 1. Electronic transmitter of frequency-modulation telegraph channel

These advantages accrue from the circumstance that positive control is maintained at all times. In transmission, a YES bit is represented by a certain frequency, and a NO bit by another frequency. This contrasts strongly with amplitude modulation, where YES is represented by the presence of a carrier, and NO is only presumed because nothing is transmitted during the intervals of all NO bits. In the amplitude-modulated, ON-OFF method, spurious impulses caused by either man-made or natural interference may be easily interpreted as YES during a NOTHING period. A second great advantage of frequency modulation also follows from the fact that YES and NO are represented by equal-valued signals of different frequencies. Changes in signal strength do not cause shortening or lengthening of the YES bit with respect to the NO. The length of each is determined only by the time interval between the frequency shifts from one to the other and not by the magnitude of the incoming envelope of carrier compared to a local reference level, as in amplitude-modulated signaling. Design objectives and automatic controls notwithstanding, attenuation changes on the vehicle carrier system do occur. Balancing, shielding, and other precautions mitigate but never completely eliminate noise. The transmission system which side-steps these hazards offers great advantage in error freedom.

The Telegraph Channel Transmitter

A brief exposition of the theory and circuitry of the standard telegraph channel terminal shows its extreme simplicity. From a read-out at the sending station, it is required only that d-c potential be applied to a loop circuit which shifts the frequency of the transmitting oscillator. The schematic arrangement of the control circuit of that oscillator is shown by Fig. 1.

The transducer which converts the coded d-c signals into corresponding frequency changes of the carrier is, in fact, only a pair of contact rectifiers.

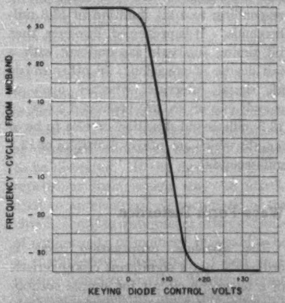

Fig. 2. Response of frequency-modulation oscillator to keying potential

"C" following a rest on "No" a "Yes" bit is followed by a "No" with timing corresponding to 75 bits per second.

Fig. 4. Time delays and wave forms in telegraph channel at 75 bits per second

When rendered conducting by the opening of the transmitter loop, the frequency of the carrier oscillator is increased. When made non-conducting by the closing of the loop, the oscillator frequency is depressed. The difference between these two frequencies is 70 cycles. The shift from one to the other takes place rather abruptly, with the trigger action specified by Fig. 2, all within the limits of a 20-volt swing in control potential. The frequency shift as observed at the output of the sending-end channel filter, however, is gradual, as dictated by the bandwidth of that filter. (The concept of amplitude time constant in a bandpass filter is a familiar one. It is commonly remembered that the time required to establish a new carrier amplitude at the output of a filter is inversely proportional to half the bandwidth. The fact that a filter has the same reluctance to accommodate a shift in frequency is equally valid, though perhaps not so generally appreciated.)

Fig. 3 shows the signal currents resulting from frequency-modulating a carrier. *A* depicts the control current delivered to the telegraph channel terminal when the information is alternate YES and NO bits. *B* shows the essentially instantaneous frequency shifts which result. *C* shows the frequency-shifted wave after it has passed through the band-limiting channel filters. Two special characteristics are of interest. The frequency change is gradual, practically sinusoidal in fact, just completing one transit in time to start the next. The frequency change is accompanied by a decrease in amplitude corresponding to each upward and downward shift. This latter characteristic is the result of eliminating products of modulation higher than the first-order side bands.

Keying Methods

Actually, a carrier transmitter may be keyed by either of several techniques. A preferred method is the opening and closing of a 2-wire loop, as indicated by Fig. 1. A simpler method, permissible when the keying machine is close to the carrier channel terminal, is the opening and closing to ground of a single wire leg. By rearrangement of the potentials applied to the channel terminal, it is permissible to key by the application of positive battery to a single wire leg. Polar battery too, with positive representing YES and negative representing NO, may be employed.

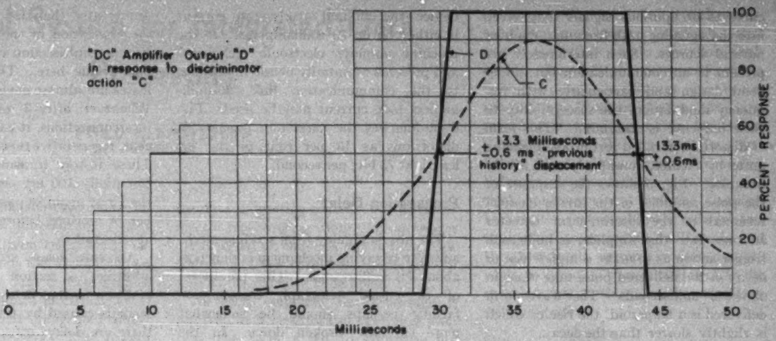
The keying may be at any rate up to and including 75 bits per second, corresponding to a bit duration of 13.3 milliseconds. It is presumed, however, that bit timing intervals are uniform with a fair degree of precision. In other words all signal intervals, whether open or closed, YES or NO, are presumed to be of 13.3-millisecond duration or else to be of lengths which are integer multiples of 13.3 milliseconds.

Wave-Form Distortion

The absolute propagation time is ordinarily not a significant characteristic of a telegraph circuit for simple station-to-station teleprinter working. Only when a communication system depends upon answer-back or error correction does transmission delay become an important matter. Relative shifts of pulse arrival time from the idealized are, however, extremely important in transmission of all forms of encoded information. In nearly all systems of record communication, some selection or gating device functions on a local receiving-end time base. Time displacement of the rise and decay transients of signaling pulses or bits from their idealized position is distortion. Measured in milliseconds, it has a concrete meaning to the terminal equipment designer. For these reasons, considerable attention is devoted to arrival wave forms and the possible conditions which may displace or alter them. Fig. 4 shows time graphs of the response of the channel as measured at the frequency-modulation detector, the discriminator. The response is shown as having a negative sign for the NO or high-frequency condition, and a positive sign for the YES or low-frequency condition. For the immediate purpose, the receiving mechanism will be presumed to be actuated when the detector voltage passes through zero. By this token, it will be noted from graph *A* that the arrival of a YES indicating crossover lags its initiation at the sending station by just under 30 milliseconds. It should be noted also that arrival wave *A* overshoots 100-per-cent response and oscillates mildly.

For the purpose of the following dissertation on wave forms it is convenient to consider a specific pattern of YES and NO bits. The presumed transmitted signal combination for curve *A* is a number of NO bits followed by a number of YES bits. If the situation is reversed and

Fig. 5. Triggered response of channel amplifier output



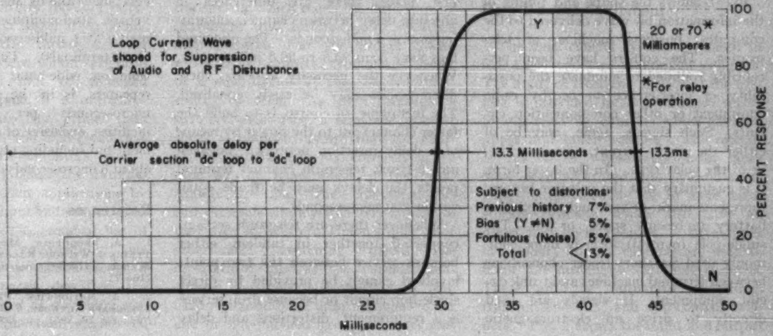


Fig. 6. Shaped signal delivered to data machine

the signals under study are a number of YES bits followed by a number of NO bits, then the transient from one to the other has the shape of curve *B*. The transition from the one to the other is presumed to have been initiated 1-bit interval later than the transition shown by *A*. Ideal transmission would, of course, require that the *A* and *B* arrivals, the points of zero crossing, be precisely 1-bit length apart. This would be only a necessary but not a sufficient criterion of perfect receiving-end signal reproduction. In perfect transmission, the arrival of any bit transient, no matter what information preceded YES or NO, must coincide with perfect bit interval timing. Any departure from ideal timing of a transient caused by the combination of YES and NO pulses may very appropriately be called previous-history distortion.

Graph *C* shows the arrival wave resulting from the transmission of a single YES bit following a number of NO bits. It is to be noted that the zero crossovers marking the beginning and ending of the pulse do not fall precisely where they would had the information content of the character been different. It is not at once apparent which timing is ideal. Speculation quickly reveals that neither beginning nor ending is the same as it would have been had the pulse train been alternate single YES and NO bits. Still, it is not obvious which timing should be called the standard. By accepted usage, the locations of the crossovers of a steady succession of alternate positive and negative bits are taken as the reference standard. Pulses shortened, lengthened, or displaced from that standard are said to be distorted. If the distortion is of a repetitious form which may be attributed to an electrical characteristic of the circuit, sluggish response, or other exhibits of nonlinearity or memory, it is said to be a characteristic distortion. Good engineering practice in the Western Union Telegraph Company holds this distortion within ± 1.0 millisecond per telegraph section.

A telegraph section is defined as that part of a circuit included between two carrier channel terminals. The section length has little, if any, relation to circuit miles. Even many transcontinental circuits are but a single section. The audio-frequency, frequency-shifted carrier generated in New York City for a Los Angeles, San Francisco, or Portland transmission is first detected and restored back to bit-length d-c pulses at the city of destination. On the other hand, the 90-mile New York-to-Philadelphia hop is a section. Transmission efficiency on the two is essentially the same.

Distortion which consistently lengthens either the YES bit or the NO bit with respect to the other is called bias distortion. Marking bias lengthens the YES at the expense of the NO, and spacing bias lengthens the NO at the expense of the YES. Bias distortion is not allowed to exceed 5 per cent of bit length.

A third source of bit-length variation is the distortion caused by noise, crosstalk, and/or whatever form of extraneous currents or spurious signals may creep into the signaling path from man-made or natural sources. Such interferences are present in all communication but, under good design and particularly with frequency modulation, the susceptibility to their influence is minimized. This form of distortion is called fortuitous, meaning quite by chance, completely and wholly irregular. Fig. 5 shows the response of the pulse amplifier of the carrier channel terminal to the discriminator detector action. Into that amplifier is built such trigger action as to make complete rise or decay of the delivered pulse take place in about 2 milliseconds. The wave form delivered is a trapezoid, the rise of which is slightly slower than the decay.

Fig. 6 shows the shape and timing of the information bit wave delivered to the computer, business machine, or teleprinter. The corners have been perceptibly rounded to eliminate the possibility of interference to nearby radio equipment or other communication circuits. Such signals, again, may be of either the single current, open or close, or of the polar type. In the latter form, it is customary that the negative battery represents mark, or YES, and the positive battery represents space, or NO. The single-pole (neutral) form is more commonly used for short feeder connections between terminal machines and trunk circuit equipment. If signals are used directly to drive an electromagnetic device, the nominal steady-state current is either 60 or 70 milliamperes. If the machine employs electronic techniques and presents essentially ohmic impedance to the communication link, 20-milliampere loop current may be used. Fig. 6 summarizes the maximum permissible distortions as 13 per cent of the bit length at 75 bits per second.

Propagation Delay

The absolute delay from sending mechanism to receiving mechanism is shown as about 30 milliseconds. This parameter of the usual telegraph transmission facility perhaps should be somewhat more carefully broken down. In the first place, there are differences in absolute delay between channels amounting to over 4 milliseconds. The measured lags vary from 25.3 to 29.6 milliseconds. Whenever the necessity appears, these discrepancies may be easily equalized. The technique, of course, is to build the faster channel out to the slower by means of a delay insertion network. Between any 2-trunk telegraph channel terminal points the delays may be made equal within 200 microseconds.

Whenever there are telegraph sections connected together in tandem, either because service between the two points involved cannot be provided by direct single-hop circuit or because drop service is a requirement, distortions and delay are greater than for the single section. Generalization in the amount of distortion on multisection circuits would be of little value here. The separate section losses are almost never directly additive. Whenever, after 3- or 4-tandem section interconnections, it exceeds about 30 per cent, regenerative repeaters are employed. These restore transmission efficiency to essentially 100 per cent, and the signals then may again be passed through a number of sections before becoming materially degraded.

Absolute delay, of course, is directly additive to section after section. In addition to that delay of about 30 milliseconds caused by telegraph equipment, there are delays caused by vehicle band equipment and by line propagation. The vehicle band equipment may be approximated at 1 millisecond per band section (two terminals). The line propagation time on wide-band systems, including repeaters, is in the neighborhood of 8 microseconds per mile. Microwave facilities, exclusive of channelizing equipment but including repeaters, account for about 6 microseconds delay per mile.

Discussion

N. D. McMullin (Lenkurt Electric Company, Inc., San Carlos, Calif.): The increased use of commercial telegraph facilities for transmission links in business data processing systems, lends emphasis to the necessary early determination of standardized high-speed data channels and to a standard number of units in the code used for this purpose since this affects both the transmission speed and the accuracy of the data.

The required telegraphic transmission speed will vary because of the considerations pointed out by Mr. Bramhall and, in general, because of the economic cost of the computer and equipment. While the 3-kc standard vehicle voice band can be subdivided into data channels of various widths to permit a choice of transmission speeds, it is probable that eventually two or three standard high-speed data channels will be established.

Mr. Bramhall suggests that a 1,275-cycle-wide half-band may prove to be an economical spectrum unit for data transmission. There is great opportunity in the future for further contribution through the co-ordination of transmission people and the computer manufacturers for determining what speeds are dictated by the economic balance of transmission costs and computer end equipment costs.

Transmission of business data consisting primarily of numerical figures must have high accuracy and, therefore, probably requires a code containing more units than the conventional 5-unit telegraph code to make necessary parity checks. The trend seems to be toward a 7-unit code for business data transmission although this has not yet been clearly indicated.

F. B. Bramhall: It is encouraging to know that a number of industry, user, and professional groups are taking cognizance of the importance of standardization in the data transmission field. The Joint Computer Conference has set up a committee charged with studying the code standardization problem as has also the Radio-Electronics-Television Manufacturers Association. Attention to speed and bandwidth requirements will presumably follow. Our own communication division is at this time organizing a technical committee to work in the computer-communication field. All of these efforts deserve the support of the record communication and computer engineers.

Control System for Integrated Data Processing

PHILIP R. EASTERLIN
MEMBER AIEE

TO MEET the increasing demands from its patrons for automation equipment, the Western Union Telegraph Company has completed the design of an extremely versatile data control system for use with high-speed electronic computers at centralized integrated data-processing (IDP) centers. This system serves as the main artery for data information which can be transmitted simultaneously from cities throughout the country over a Western Union telegraph network. As each unit of classified information is received, it is automatically processed into the proper data category for efficient and high-speed programming by modern computers.

This development opens the automation field to many new applications by providing the vital input and output communication needs for economical use of expensive computing equipment at one centralized point in the patron's scope of operations. This paper describes the new system designated as switching system *203-A*, which has been engineered for initial use in Sylvania Electric's new data-processing center at Camillus, N. Y.

General Application for Sylvania Electric

The data-control system, as applied by Sylvania Electric, is connected by a Western Union private-wire telegraph network to their larger plants located throughout the United States. Over this network, which is also used for administrative messages between any two or more offices data messages are originated at any of the outlying plants and contain three data-routing characters corresponding to a particular data category. Such messages are then transmitted over the wire network into one of a number of input or reperforator receiving positions of the data-control equipment located at the data-processing center. At the reperforator receiving positions, data messages are received on chadless reperforator tape containing the printed characters as well as the punched code holes.

As each complete data message is received at a reperforator receiving position, the tape is fed to an intraoffice transmitter which reads the data-routing characters and automatically switches each message over the proper 5-wire 150-word-per-minute crossoffice circuit to a reperforator at the selected data-storage position. As each message is switched crossoffice, a sequence number check is made to assure that the characters are being punched correctly in the tape by the reperforator at the data-storage position. The crossoffice circuit principle employed is very similar to that used in Western Union's plan *21-A* reperforator switching offices. The reperforator tape at the various data-storage positions is wound on a reel, each reel containing data messages under one or a combined group of categories such as payroll, invoices, inventory, etc.

The classified data on individual tape reels of various data-storage positions are periodically removed, and the reperforator tape is then fed into a converter associated with the electronic computer, in this case Remington Rand's Univac. The converter translates the data information from the reperforator tape into punched card form, and the cards are then used in the conventional manner to transmit onto the magnetic tape of the uniservo units associated with the computer. A reperforator tape-to-magnetic-tape converter is now under development and may be used to by-pass the punched card operation.

In subsequent computer operations, Univac is programmed to process individual data subjects such as hourly, daily, or monthly payroll, invoices, production forecasts, etc., which have been gathered and combined from a number of plants throughout the country. When required, the telegraph network is also used for transmitting information from the data-processing center back to the plant.

A block diagram of the Western Union telegraph network for Sylvania Electric is shown in Fig. 1. Administrative messages can be exchanged directly between any of the offices on the same telegraph circuit. In addition, messages between Sylvania plants on different circuits are relayed by Western Union torn-tape reperforator switching centers located at Camillus, N.Y., Williamsport, Pa., and Salem, Mass. Data messages from any Sylvania plant associated with this network are transmitted into the Camillus IDP center, processed by the data-control equipment, programmed to Univac, and the returnable computer information, when required, is transmitted back to the specified plant through the torn-tape switching centers.[1]

Data Control Equipment

The data control system is housed in five basic types of equipment cabinets. The input or receiving portion of the system is provided by one or more reperforator receiving cabinets which have an upper and lower position. The output of this system where reperforator tapes have been separated into specific categories, is provided by one or more data-storage cabinets, which also have an upper and lower position. Three types of auxiliary control cabinets are used to house the automatic switching controls. These are the automatic switching, transmitter-finder, and autocontrol cabinets. Fig. 2 shows the input and output cabinets, which are similar in appearance, and Fig. 3 shows the group of three auxiliary control cabinets.

For the Sylvania application of the data-control system, the auxiliary control cabinets are packaged to provide a maximum of 50 input or reperforator receiving positions and 50 output or data-storage positions. However, additional input and output positions can be provided, as required, by expanding the switching control equipment.

Preparation of Data Messages at Outlying Offices

Data or administrative messages at various Sylvania plants are originated on Western Union's standard type-*19* sets in the form of a manually prepared perforated tape. This tape passes through a tape transmitter that sends the message characters over carrier or physical line circuits to the distant point and provides a printed monitor copy. On circuits having more than one office, a local selector controls transmission and reception. The selector prevents the transmitter from starting until the cir-

cuit is idle and allows only the selected stations to copy the transmission.

All data messages destined for the IDP center at Camillus have a message-beginning *Z* character, followed by the routing prefix characters *figures F*, the three data routing characters—the first of which is always the identifying letter *D*—and the message-ending characters of three *carriage returns*. Data messages are either transmitted directly to the data-control system or are relayed to this equipment by means of the torn-tape switching centers. Messages of a administrative nature are preceded by appropriate routing characters and are manually routed to their proper destinations when relayed by the torn-tape switching centers.

Reception of Data Messages

Fig. 4 shows in block form the principles employed in simultaneously receiving data messages from many outlying offices over a telegraph network and in automatically routing each unit of data information into a selected category, as determined by the data-routing characters inserted by the distant or originating office. Messages arrive at the reperforator receiving positions on a printer perforator at 75 words per minute. As the tape is printed and reperforated, it is fed through a newly designed loop-gate intraoffice transmitter.

Upon reading the designated message-beginning character, this transmitter automatically shifts its tape gate to the left and develops a loop of tape while idling and searching for the routing prefix characters embodied some distance from the beginning of the message tape. Upon locating the routing prefix characters, the transmitter stops momentarily until signaled to transmit the three data-routing characters which are used for automatic switching purposes. After transmitting this control information, the tape gate is restored to the normal or right-hand position and, while restoring, the loop of tape is smoothed out to the original starting position, whereupon the complete message tape is then transmitted. Fig. 5 shows two of these transmitters with the tape gate in both positions of operation.

CONNECTION TO AUTOMATIC SWITCHING UNIT

When the message-ending control of three *carriage returns* has been read on the incoming printer perforator, a message-waiting indicator is advanced one step. This indicator is an add-and-subtract unit which indicates the number of unswitched messages by advancing one point on each message-ending signal and subtracting one point for each message switched crossoffice. As the message-waiting indicator is stepped off the zero position, indicating one complete message to be switched, and the intraoffice transmitter has read the routing prefix *figures F*, a request is now made to an automatic switching unit having director equipment capable of serving a group of 12 intraoffice transmitters.

As the automatic switching unit is connected to this particular intraoffice transmitter, the three data-routing characters are received from the transmitter and stored on selector relays located in the automatic switching unit. Contacts on these relays form character-reading

circuits which interpret the three data-routing characters. As these characters, representing any one of a number of data categories, are stored, they cause a rotary-type route switch associated with this intraoffice transmitter to step to the proper stator point corresponding to the selected data category or data-storage position. As this action which requires 3 or 4 seconds is completed, the automatic switching unit disconnects and performs a similar cycle of operation for other intraoffice transmitters having messages to be switched over the crossoffice circuits.

The automatic switching unit, in addition to performing its normal switching functions, also detects administrative messages which have been misrouted into the data-control equipment, or data messages which contain improper or unregistered data-selection characters. For example, in the case of misrouted administrative messages, the director equipment recognizes the absence of *D* as the first of the three data-routing characters and such messages are automatically switched to an intercept data-storage position where they are retransmitted to a receiving-only position for manual handling. However, if *D* is the first of the three data-routing characters, but the following two characters do not represent a valid data category, the tape is held in the intraoffice transmitter and the supervisor is automatically summoned.

ACTUATING TRANSMITTER FINDER

After the automatic switching unit has directed the route switch to the proper stator point, corresponding to the three data-routing characters, the intraoffice transmitter waits for a ground at its individually assigned point on a ring-type transmitter allotter. The transmitter allotter has a rotating wiper which sequentially sweeps all points on the ring every 3.3 seconds and is grounded through the contacts of an allotter-control relay. As an individual transmitter receives an allotment, this relay removes ground from the allotter wiper until this particular crossoffice connection has been completed, thereby preventing two simultaneous connections to the same data-storage position. When an intraoffice transmitter is actuated in this manner, the transmitter finder switch representing the selected data-storage position is initiated, and this switch steps to a marked point corresponding to the intraoffice transmitter seeking connection.

CONNECTION TO THE SELECTED DATA-STORAGE POSITION

As the transmitter-finder switch is properly positioned, relay-control circuits are actuated to complete the crossoffice connection between the intraoffice transmitter at the reperforator receiving position and a 5-wire reperforator located at the selected data-storage position. The 5-wire circuit between these two apparatus units is made through five heavy-duty contacts on a free-running impulse unit operating at 150 words per minute. The five crossoffice intelligence pulse circuits, including a sixth conductor for the step circuit of the intraoffice transmitter, are shown in Fig. 6.

CROSSOFFICE TRANSMISSION

Before crossoffice transmission begins, an automatic numbering machine at the data-storage position—consisting of four rotary switches which are arranged to transmit on a 5-wire basis through the impulse unit—transmits the next consecutive message number characters into the reperforator. Following this number, relay-control circuits connect the impulse unit and the associated intraoffice reperforator to the five crossoffice conductors of the intraoffice transmitter position. Similar control circuits at this position now function to establish proper synchronism with the free-running impulse unit by absorbing the first transmitter step pulse before completing the circuit to the intraoffice transmitter.[2]

The 5-wire reperforator used at the data-storage position, in addition to punching the code holes, is eqpuiped with five read-back transmitte contracts located five characters to the left of the tape punch block that perforates the chad-type holes. Five character operations after a particular character is transmitted into this reperforator, the code holes for this character appear over the read-back contacts. These contacts are connected to the five crossoffice pulse conductors and, as the reperforator punches the code holes of each new character, the read-back contacts close and transmit the fifth previously received character back to the intraoffice transmitter position.

SEQUENCE NUMBER CHECK

Each data message switched crossoffice by the intraoffice transmitter is preceded by a sequence number of about 10 characters which is inserted by an automatic numbering machine located at the distant sending end of the circuit transmitting to

the data-control system. As these characters are transmitted crossoffice, the read-back contacts on the reperforator at the data-storage position function to transmit back the punched intelligence over the same 5-wire crossoffice conductors and, during this sequence number check, transmission is at half speed, or 75 words per minute. For example, a character is sent from the intraoffice transmitter to the reperforator and, while the code holes are being perforated in the tape, the read-back contacts function to transmit the fifth character previously received back to the intraoffice transmitter position.

These read-back signals are received electronically at the intraoffice transmitter position and are compared on a sequence number indicator having several rotary switches which maintain the sequential numbering pattern. If each of the sequence number characters compares correctly, the intraoffice transmitter is allowed to transmit the next character, etc. This cycle of operation continues until the three identifying characters and a 3-digit number are compared correctly, after which time the comparison circuit is disabled and the remainder of the message is transmitted crossoffice at the normal speed of 150 words per minute. Failure to compare the sequence number actuates automatic test equipment which performs an immediate check on the equipment involved in the crossoffice connection. This action is described later.

When the end-of-message signal, consisting of three *carriage returns*, is transmitted into the data-storage reperforator, the intraoffice transmitter is stopped and the crossoffice circuit is disconnected. This particular data-storage position is now in readiness to receive a crossoffice connection from other intraoffice transmitters having messages prefixed with the same three data-routing characters.

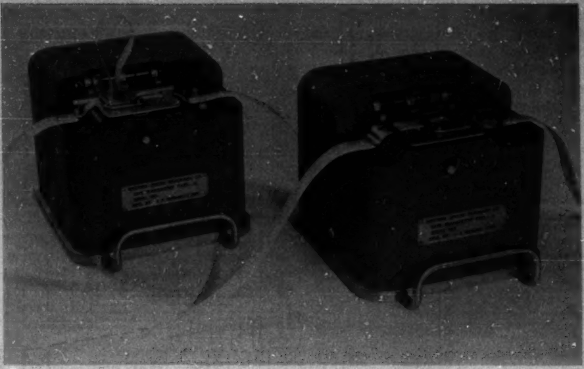

Fig. 5. Intraoffice transmitter

Failure to Compare Sequence Number Correctly

If a wrong comparison occurs on the sequence number check, which can be caused by improperly prepared tape or equipment trouble, the intraoffice transmitter is immediately stopped and the supervisor is summoned. In the meantime, an automatic equipment test is made on this particular crossoffice circuit by an automatic "bust this" unit. This unit functions to cut into any crossoffice circuit where a wrong comparison has occurred and transmits the words *bust this*, followed by the end-of-message signal, into the reperforator at the data-storage position. As these test characters are punched in the reperforator tape, they are transmitted back and compared by the automatic "bust this" unit in a manner similar to the normal sequence number check. If a correct comparison of the test characters is made indicating that the reperforator is functioning properly at the data-storage position, the end-of-message signal following the words *bust this* releases the crossoffice connection and automatically restores the data-storage position to service. Under this condition, the tape is retained in the intraoffice transmitter for the attention of the supervisor. Failure of the test characters to compare properly with the automatic "bust this" unit indicates crossoffice equipment trouble to the data-storage position and the connection between the intraoffice transmitter and reperforator is retained for the attention of the supervisor; in addition, the testing and regulating attendant is alerted.

Multichannel Data-Storage Positions

Provision is made for patching any two or more data-storage positions together to form a multichannel data category to meet conditions where the hourly or daily traffic load exceeds the capacity of one data-storage position. This is performed by a channel patch board located in the autocontrol cabinet. Also, if the capacity of a single data-storage position is unexpectedly exceeded, supervisory attention is automatically directed to this condition when the crossoffice holding time—inability to obtain the desired data-storage connection—exceeds 2 minutes from any one of the intraoffice transmitter positions.

Traffic Routing

The automatic switching unit, which interprets the data-routing characters and automatically positions the route switch associated with each intraoffice transmitter, contains a traffic-routing board which provides complete flexibility in the choice of routing and grouping data messages into any of the data categories. By means of a 2-conductor patch cord, the data-routing characters can be reinterpreted to combine several categories into one data-storage position. For example, it may be desired to group lightly loaded categories on a particular day so that invoice data (DID), production schedules (DPS), inventory reports (DIR), or other specific categories will be received at one data-storage position. Such reassignment or grouping makes it possible to associate the data-storage positions normally assigned to these categories to multichannel purposes on other heavily loaded categories.

LOCAL REDISTRIBUTION OF DATA MESSAGES

Where several different data categories have been grouped into one data-storage position, it is possible to rerun the reperforator tape from this particular tape reel through the system for redistribution on a local basis. For example, it may be desired to accumulate the following data subject matter into one data storage position for redistribution later: payroll hourly (DPH), payroll daily (DPD),

payroll weekly (DPW), and payroll monthly (DPM).

By changing the data routing or grouping pattern at the traffic-routing board and rerunning the tape through one or more intraoffice transmitters located at available reperforator receiving positions, the four data categories mentioned in the foregoing may be redistributed to four separate data-storage positions. When data information is reprocessed locally, the normal operating features of the system are retained, including the sequence number check of each data message.

Automatic Switching to Distant Offices

While the data-control system has been designed for meeting the IDP requirements of Western Union's patrons, it also may be used for automatically switching administrative messages to distant offices. This additional operating feature was considered in the design of the data-storage positions, which are arranged to accommodate a line transmitter between the reperforator and the tape reel for retransmission of the perforated tape to distant offices. When used in this manner, the system will function in some respects like Western Union's high-speed reperforator switching centers, now operating in 15 of the larger offices throughout the country.

A Video Visual Measuring Set with Sync Pulses

P. T. SPROUL
MEMBER AIEE

Synopsis: This test set is designed to make gain-frequency measurements of a video transmission circuit over the range of 100 kc to 10 mc (megacycles) and present the characteristic on an oscilloscope. The test signal is arranged to include a simulated horizontal synchronizing pulse for use on video circuits equipped with pulse operated devices such as clampers. It is intended for operation where the transmitter and receiver are at separate locations. Provision is made at the receiver for quantitative determination of gain deviation and frequency.

THE OPERATION and maintenance of video transmission circuits requires an easy and rapid means of making gain-frequency measurements. Such information is needed, first, to determine the condition of circuits in service and, second, to assist in making the required adjustments. To meet this need, a video test set has been designed by the Bell Telephone Laboratories which presents the gain-frequency characteristic on an oscilloscope. This set sweeps the video band from 100 kc to a maximum of 10 mc.

A video facility in the telephone plant as furnished to the customer is usually composed of several circuits in tandem, each containing various kinds of equipment. The problem of measuring such facilities has been complicated by the use of clampers and other devices requiring the presence of horizontal synchronizing pulses for proper operation. This transmission-measuring set provides for the optional inclusion of simulated television horizontal synchronizing pulses in the test signal and means in the receiver for measuring in their presence. It was originally intended for the measurement of *TD-2* radio relay circuits on a video-to-video basis, but it can be used on most types of video circuits. In its present form it cannot be used for accurate measurements of coaxial facilities, as the sweeping test signal would interfere with pilot signals used on those systems for gain regulation.

The video test signal used is a sine wave which varies linearly in frequency over the desired video range with a repetition rate of about 70 cps (cycles per second). This rate was chosen from two considerations: First, it is undesirable to sweep at the usual power line frequency rate of 60 cps, as the presence of extraneous power frequency energy cannot be separated from the desired gain-frequency information. With the rate chosen, 60-cycle interference results in multiple traces and is immediately apparent. Second, to obtain maximum resolution, the sweep repetition rate should be as low as possible consistent with excess flicker in the presentation. The receiver switches on alternate sweeps of the transmitter between the signal received from the circuit under test and a single frequency signal of known power, providing a flicker rate of one-half the repetition rate. The rate chosen provides a negligible amount of flicker on the usual *P1* phosphor screen.

The line-synchronizing pulses, having the standard 15,750-cps repetition rate, are switched on when required to operate the clampers of the circuit under test, as already mentioned. They have no function in the test set receiver. In distinction, the oscilloscope is synchronized at 70 cps, the sweep repetition rate, by circuits in the receiver which recover this frequency from the received signal. The wave form of the composite test signal is shown in Fig. 1, where the voltages represent the maximum amplitude available from the transmitter. The sine wave portion of the signal is equivalent to a power of −10 dbm (decibels referred to 1 milliwatt) in a 75-ohm circuit, the nominal impedance of the transmitter and receiver.

System Operation

As shown in the block diagram of the system in Fig. 2, the test set is divided into a transmitter and a receiver for use at the ends of the facility being tested. The transmitter generates the test signal and consists of the video sweep generator and the synchronizing pulse generator. These are assembled with the necessary power supply in a portable unit, as shown in Fig. 3. The unit may be removed from the carrying case and may be rack-mounted, if desired. A video attenuator is provided to control the composite output voltage over a maximum range of 20 db (decibels) in 1-db steps. A sync-amplitude control permits varying the amplitude of the synchronizing pulse.

Paper 56-673, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 29, 1956; made available for printing May 15, 1956.

P. T. Sproul is with Bell Telephone Laboratories, Inc., Murray Hill, N. J.

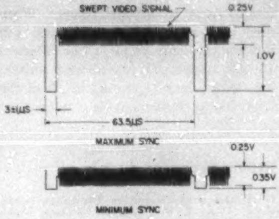

Fig. 1. Test signal wave form

Thus, the per cent of synchronizing pulse may be set as desired.

The receiver provides for detecting the sweeping video test signal and presenting the envelope of the sine wave portion on the scope with gain and frequency calibration information. The amplitude modulation envelope of the sine wave signal results from gain deviations versus frequency of the circuit under test. These circuits and their power supply are assembled into the portable unit shown in Fig. 4. A video attenuator permits varying sensitivity of the receiver over a 20-db range. Controls are also provided for positioning the calibration trace, for setting the frequency marker, and for adjusting the receiver presentation to be in synchronism with the transmitter repetition rate.

When the received test signal does not include the sync pulse, it is applied directly to the amplifier-detector. A filter is used at its output to separate the wanted envelope information from the original signal. This filter is of the constant resistance type having a nominal cutoff of 25 kc, and it has good transient response. The cutoff frequency of the filter represents a balance between achieving as low a frequency of measurement as possible and obtaining adequate resolution in the measurement.

It is obvious that measurements cannot be made below the cutoff of the filter because the wanted envelope information cannot be separated from the original signal information. In addition, the transient response of the filter makes the practical minimum frequency of measurement somewhat higher than the nominal filter cutoff. A value of 100 kc is reasonable for the filter used here.

The filter cutoff must be high enough to obtain reasonable resolution. Allowing about 1.5 milliseconds for receiver switching, the useful duration of the transmitter sweep is about 12.5 milliseconds. When sweeping the entire 10-mc band, this corresponds to a rate of change of sweep frequency of approximately 800 cps per microsecond. Assume that the characteristic being measured is a sine wave over the entire video band, equivalent to a single echo. The maximum envelope frequency that the filter will transmit without attenuation is 25 kc or a sine wave having a period of 40 microseconds. With the sweep speed mentioned, the sweep will change in frequency 32 kc in 40 microseconds; therefore this is the finest ripple that will be presented at its true amplitude. Such resolution is adequate for the usual video circuits.

The presence of the sync pulse in the signal causes improper operation of the detector in the receiver. To detect the envelope of the sine wave signal in its presence, the incoming composite signal is passed through a high-pass filter. This filter removes most of the energy in the sync pulse, permitting the detector to operate normally. It is possible to separate these two signals on a time basis, but the additional complexity was not justified for this application. The characteristic of the high-pass filter is shown in Fig. 5. The cutoff frequency was determined experimentally to be as low as possible consistent with proper detector operation. As the figure shows, the nominal value is of the order of 250 kc. The use of this filter increases the lowest frequency at which measurements can be made to about 500 kc. Because of this, provision is made for switching it out when sync pulses in the test signal are not required. It should be noted that the 25-kc filter at the output of the detector is switched out when the high-pass filter us used. This is necessary because of its poor transient response in the presence of the residual sync pulse information. A filter with a higher frequency cutoff was not necessary because of the nominal 200-kc cutoff of the oscilloscope used.

The input to the receiver is switched on alternate sweeps of the transmitter between the incoming signal and a single frequency signal of known power whose level can be varied by means of a calibrated attenuator. This gives the receiver presentation shown in Fig. 6. The determination of gain deviations can be made by superimposing the calibration trace on the line trace at the points of interest and reading the relative gain from the calibration attenuator. This makes the results independent of

amplifier-detector or oscilloscope gain settings and dependent only on the attenuator accuracy and the flatness of the transmitter and receiver gain frequency characteristic. D-c transmission is provided between the detector and the d-c oscilloscope to permit independent motion of the two traces when manipulating their respective attenuators, which makes operation of the set simpler. The frequency marker may be set to any frequency desired over the 100-kc to 100-mc range.

The set is designed so that the transmitter and receiver can be operated at the ends of a 1-way circuit. In addition to the necessity of providing for synchronizing the receiver presentation with the transmitter, this places stringent requirements on the gain-frequency characteristic of each unit. It is essential that the transmitter work with any receiver in the system, and vice versa. The only practical way to achieve this is to have each unit as flat as possible.

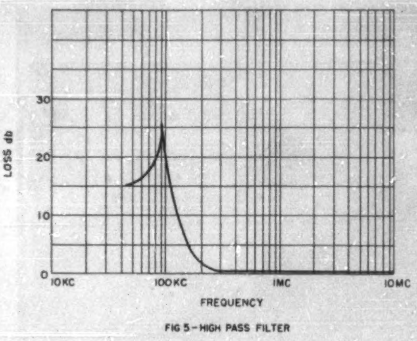

Fig. 5. High-pass filter characteristic

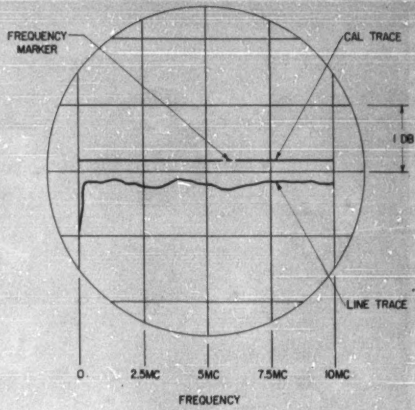

Fig. 6. Oscilloscope presentation

For this, the receiver video circuits were conservatively designed and can be aligned, using a thermocouple as a standard, to within ±0.02 db over the 100-kc to 10-mc band. The receiver, after alignment, is used to adjust the transmitter. A typical set can be adjusted on a back-to-back basis to be flat to within ±0.03 db over the entire 10-mc band. The residual deviation of the set has a period of the order of 5 mc. It is of interest to the television engineer that this is equivalent to a 0.2-microsecond echo which is 50 db below the signal. In discussing the influence of echos on a television picture, Mertz[1] reports subjective data showing that an echo having this delay is barely perceptible at about 25 db below signal. There is therefore considerable margin in the performance of this test set. The accurate measurement of finer structure deviations is readily accomplished without being masked by test set deviations.

Receiver synchronization, frequency marker, and scope presentation circuits are controlled from the incoming signal. These operate to keep the receiver presentation in synchronization with the transmitter and to provide the continuously variable frequency marker appearing on the calibration trace.

Transmitter

The transmitter is shown in block diagram form in Fig. 7. The swept video signal is the difference frequency between a fixed 80-mc oscillator and a variable 70- to 80-mc oscillator and is generated in a silicon diode modulator. The variable 70- to 80-mc oscillator is controlled by a 70-cycle saw-tooth generator of conventional design. The panel controls shown make possible adjustment of the video sweep range of the transmitter. The low-frequency adjustment (LF ADJ) sets a voltage to which the positive excursion of the saw-tooth wave is clamped. This corresponds to the low-frequency end of the video output. The high-frequency adjustment (HF ADJ) sets the amplitude of the saw tooth and determines the high-frequency end of the video output. The provision for clamping the positive peak of the saw tooth provides for changing the high-frequency end of the sweep without affecting the low-frequency end setting, thus simplifying adjustment.

A simplified schematic of the video sweep generator is shown in Fig. 8. The 70- to 80- mc sweep oscillator is of the reactance tube modulated phase shift type as described by Dennis and Felch.[2] A high-transconductance pentode is used for the reactance tube and a triode for the oscillator. Three of the elements of the transmission line are adjustable as shown. They are set to give the desired sweep range with maximum flatness with the use of a fixed amplitude of saw-tooth voltage on the reactance tube grid. The buffer amplifier feeds an equivalent T transformer to match it to the low-impedance modulator. This is adjusted for maximum flatness over the 70- to 80-mc range of the oscillator with a suitable detector connected to the output of the transformer. The 80-mc oscillator is crystal-controlled, thus eliminating the problem of measuring frequency during alignment. Its buffer amplifier drives a transformer with a tuned primary. The secondary of this transformer is balanced to ground and connects to the balanced input of the silicon varistor modulator. The 70- to 80-mc oscillator provides the high level input to the modulator, and the clipping which results aids in reducing output amplitude variations as the frequency is swept. The video output power is determined by the 80-mc input voltage to the modulator which is set by a capacity potentiometer in the grid of the 80-mc buffer. Filters are provided as indicated to suppress the high-frequency energy in the video output. As the impedance of the modulator is of the order of 100 ohms, a matching pad is provided to give the desired 75-ohm output. This also acts to improve the output impedance of the transmitter.

The sync pulse generator consists of a 15,750-cps sine wave oscillator triggering a multivibrator to generate the desired sync pulse. This pulse is applied in a positive direction across the cathode of the 80-mc buffer in the sweep generator to turn off the sine wave energy during the sync pulse interval. It is also applied in a negative direction through a large resistor across the output of the video sweep generator to add the pulse during the blanking interval. Wave forms are shown in Fig. 7.

A repeating coil and equalizer is provided to permit measuring the 124-ohm balanced circuits used extensively in the telephone plant. They have an insertion loss of about 0.6 db and are flat over the 100-kc to 10-mc range to within ±0.02 db.

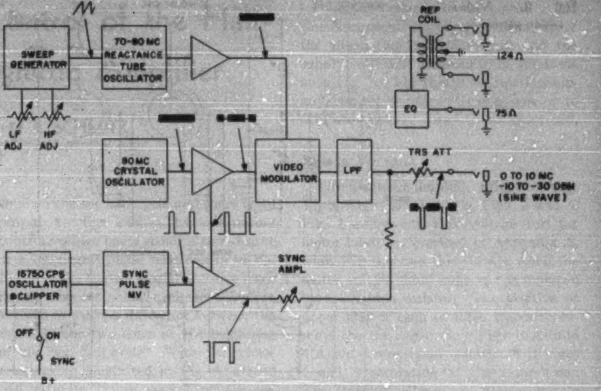

Fig. 7. Transmitter block diagram

Receiver

The block diagram of the receiver is shown in Fig. 9. Two inputs to the receiver are provided. The signal from the equipment under test is normally applied to the IN *A* jack. The following video attenuator provides for adjustment of the incoming signal power to the nominal receiver operating value of −20 dbm. The incoming signal is bridged at this point with a 1-stage video amplifier to feed the receiver presentation circuits. The high-pass filter follows. The second input to the receiver, the IN *B* jack, is normally connected to a 5-mc oscillator whose power output is variable in known amounts. The power at the CAL OSC jack is initially set up to be −20 dbm when the calibration attenuator CAL ATT is set to zero dial reading. The attenuator then provides for varying the power of the calibration signal ±4.4 db in 0.2 db steps.

Details of the video switch and amplifier-detector circuits are shown in Fig. 10. The two inputs are terminated in cable impedance using 75-ohm resistors. The switch transfers the grid of the video amplifier stage from one terminating resistor to the other. This is possible because the specially designed switch has a parasitic capacity to ground of only 7 micromicrofarads. It is of the reed type with mercury contacts and, as used in this set, has an average operating time of about 1.5 milliseconds. The video amplifier consists of one stage using a high-transconductance pentode with a simple plate-peaking circuit. It drives an envelope detector using two silicon diodes. This type of detector was chosen to minimize errors arising from the effect of harmonics generated either in the transmitter or in the circuit under test. Harmonics 25 db below the fundamental will cause an error of only 0.01 db in the output of this detector. As used, the output is balanced, and the following amplifier stage not only provides for d-c amplification but also translates to an unbalanced output to feed the oscilloscope. The input to the oscilloscope must, of course, be with reference to ground. The translation from the plate voltage of the d-c amplifier to ground is accomplished by using a divider and a 90-volt bucking battery of the portable radio type. Although the use of a battery for this purpose might seem undesirable, the severe requirements on ripple and voltage stability of the alternative regulated negative supply indicated a substantial saving in size and complexity by the use of the battery. The battery units have essentially shelf life as their load is the 2-megohm input impedance of the scope. The SCOPE POS control provides for exact balance of the output voltage to ground and is used for vertical positioning of the scope picture.

The receiver presentation circuits fed from the video bridging amplifier perform the functions of providing the frequency marker and generating the scope display. One output from the bridging amplifier is introduced into a detector together with the output of a video marker oscillator. The signal generated by this detector in the region of zero beat is amplified and shaped for applying to the *Z* axis or intensity grid of the oscilloscope. The marker generated is a blanked spot at the frequency of the video marker oscillator. In the center of this blank spot is a flickering dot which is the point at which the sweeping input goes through zero beat with the fixed marker oscillator. It flickers because of the random phase at which zero beat occurs. Considerable amplification and clipping action is provided in the pulse-shaping circuits to make the frequency marker independent of signal voltage input over a wide range.

The marker oscillator is of the beat oscillator type in order to obtain the entire range of 0 to 10 mc on one dial scale. It operates by beating a crystal-controlled 80-mc oscillator against a 70- to 80-mc variable oscillator in a silicon diode modulator. The output is at one milliwatt and the marker circuit may be energized alternatively by any oscillator providing this power. Relatively good frequency accuracy is achieved by the use of high-quality components and rigid mechanical design. An accuracy of 100 kc may be expected.

The second output from the bridging amplifier feeds a resistance-capacitance low-pass filter and a detector, forming a simple discriminator. Its output is a crude saw tooth, but the flyback portion is an accurate indication of the time at which the transmitter retraces. This is used to synchronize a blocking oscillator in a circuit similar to the vertical sync circuit of a television receiver. The output pulse of the blocking oscillator controls the receiver presentation. It triggers the switch multivibrator which is of the bistable type, switching at half the transmitter repetition rate. This operates the video switch, causing the input to the amplifier detector to be connected to the incoming signal or calibration signal on successive transmitter sweeps. The switch multivibrator also provides a square wave for the *Z* axis mixer for the purpose of presenting the frequency marker only on the calibration trace. This avoids obscuring the gain-frequency information at the frequency of interest.

The blocking oscillator pulse performs two other functions. It triggers a scope sweep generator and a blanking multivibrator. The scope sweep generates a saw tooth which is applied to the horizontal input to the scope. The blanking multivibrator is of the monostable type and generates a pulse about 2 milliseconds long. This is used to blank the scope during the operate time of the video relay. The three signals required for the intensity grid of the scope are combined in the mixer.

A repeating coil and equalizer are also provided in this unit to permit measuring 124 ohm balanced video circuits.

Summary

The test set described has been found very useful in the measurement of video circuit transmission. For straightaway use, the accuracy is of the order of ±0.05 db. It can be used for the measurement of passive devices having a loss of as much as 10 db with full sensitivity.

Alternating Current Control of the Half-Wave Bridge Magnetic Amplifier

T. BERNSTEIN

N. L. SCHMITZ
ASSOCIATE MEMBER AIEE

RECENT developments in transistors indicate great promise for a high-gain, high-power-output servo amplifier consisting of a transistor preamplifier in combination with a fast-response half-wave bridge magnetic power amplifier. Existing literature on this type of magnetic amplifier does not discuss certain problems inherent in applying this device as an output stage fed by an a-c preamplifier.[1,2] Among these are the problems of reduced output as a result of large control signals, and variation in operation caused by different types of load.

This paper considers various wave forms originating in the magnetic amplifier with the aim of providing a better understanding both of normal operation and of overdriven operation during which output is reduced as a result of large alternating voltage control signals. The effects of various types of load upon firing angles are studied both through theoretical analysis and through investigation of experimentally determined wave forms.

Operation With Alternating Voltage Control

The half-wave bridge magnetic amplifier considered in this paper is shown in Fig. 1. It uses two identically wound cores, each of which is wound with a control winding, two load windings, and a reset winding. The instantaneous polarity of V_S is shown in Fig. 1 for the set half-cycle. Reset windings, N_{R1} and N_{R2}, have their circuits so adjusted that in the absence of a control signal, the cores are reset to equal flux levels before the beginning of each set half-cycle. Both cores then reach saturation at the same time on the set half-cycle and there is no output to the load. The alternating control voltage bears either a zero-degree or a 180-degree phase relationship to V_S, Fig. 1. The control magnetomotive force during the reset half-cycle is therefore such as to cause a difference between the fluxes of the two cores at the beginning of the set half-cycle. With the phase relationship illustrated in Fig. 1, core 2 will saturate before core 1 on the set half-cycle. After the saturation of core 2, and until core 1 reaches saturation, there will be an output to the load. The load is then shunted by the windings on the saturated cores. If the phase of the control voltage is shifted 180 degrees, core 1 reaches saturation before core 2 and thus an output voltage of opposite polarity is obtained.

As the control voltage V_C of Fig. 1 is increased, the output voltage across the load increases until V_C reaches a value such that core 2 remains saturated for the entire set half-cycle. If circumstances warrant, the design of the circuit can be such as to prevent core 1 from saturating during any portion of the set half-cycle. This is a condition for maximum output. As the control voltage is increased, the output voltage tends to limit at its maximum value.

A further increase in control voltage causes the output voltage to decrease. This effect is shown in Fig. 2 for the magnetic amplifier described in Appendix I. This reduction of output voltage with large alternating control voltage is a serious problem when an electronic or transistor preamplifier is used, since large error signals to the input of the preamplifier cause a very large control voltage to appear at the control input of the magnetic amplifier. This large signal in turn causes the output voltage to drop well below its maximum value. When direct control voltage is used, there is no reduction of the output voltage for large control signals.

Explanation of Wave Shapes

To provide a more detailed understanding of the operation of this type of magnetic amplifier, wave forms are shown for various portions of the circuit. For this discussion, the phase relationship of the alternating control voltage and the supply voltage is assumed to be the same as in Fig. 1. For this phase relationship, any control signal will cause core 2 to saturate before core 1, as described.

BRIDGE VOLTAGE

The magnetic-amplifier bridge voltage V_{12} of Fig. 1, is shown in Figs. 3 and 4. Fig. 3 represents this voltage for the motor load, as described in Appendix A, while Fig. 4 shows this voltage when the motor and its shunt capacitor is replaced by a 390-ohm resistor. The positive or upper half of each of these traces represents the set half-cycle. Figs. 3(A) and 4(A) show zero signal operation with cores 1 and 2 saturating at the same time. The bridge voltage is approximately equal to the supply voltage V_S until both cores saturate. This is true since the voltage drop through R_S caused by the exciting current is negligible. After both cores saturate, there is an abrupt drop in bridge voltage because the impedance of the saturated cores is much less than R_S. Figs. 3(B) and 4(B) show the bridge voltage when a small control signal (less than that required for maximum output) is applied. Until core 2 saturates, the bridge voltage is approximately equal to the supply voltage. After core 2 saturates, the bridge voltage is reduced as a result of the increased voltage drop through R_S caused by the load current. When core 1 saturates later in the set half-cycle, the bridge voltage drops to a low value as a result of the low saturated impedance of both cores. Fig 3(C)shows that with the motor load, core 2 is saturated for the entire set half-cycle, while core 1 never reaches saturation. For the resistance load, Fig. 4(C) shows that at maximum output core 2 is saturated for the entire set half-cycle, whereas the time of saturation of core 1 (the second core to saturate) is almost unchanged from the quiescent condition. This phenomenon is explained in the section "Determination of Firing Angles."

Figs. 3(D) and 4(D) show the bridge voltage after the load voltage has begun to decrease as a result of excessive alternating voltage control. The figures show that the sharp drop in the bridge voltage at the trailing edge of the set half-cycle advances as the control voltage is increased. This advance results in less output voltage. Since the sharp drop is a result of the saturation of core 1, reduction in output must stem from early saturation of core 1.

Paper 56-626, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted October 17, 1955; made available for printing April 12, 1956.

T. BERNSTEIN is with General Motors Corporation, Milwaukee, Wis., and N. L. SCHMITZ is with the University of Wisconsin, Madison, Wis.

This work is an extension of studies conducted by Mr. Bernstein as a thesis in partial fulfillment of the requirements of the degree of Master of Science at the University of Wisconsin.

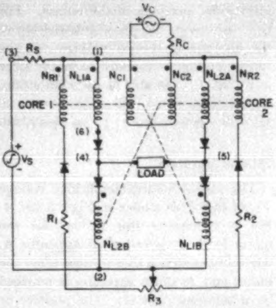

Fig. 1. Half-wave bridge magnetic amplifier circuit

Rectifier Voltage

The voltage V_{64} of Fig. 1 is shown in Fig. 5. Fig. 5(A) through 5(D) represent operation with control signals ranging from zero (quiescent condition) to a value large enough to cause output drop-off; see Fig. 5(D).

During the reset half-cycle, the rectifier voltage is such that point 4 is positive with respect to point 6. This is a nonconducting condition. As the control signal is increased, the voltage V_{46} can be seen to decrease. At first glance, it might be suspected that voltages induced in N_{L1A} and N_{L2B} by windings N_{C1} and N_{C2} respectively should be equal and opposite and have no effect in reducing V_{64} during the reset half-cycle. However, such is not the case, because of of the saturated condition of core 2 at the beginning of the reset half-cycle. Since N_{C1} tends to drive core 1 out of saturation, winding N_{L1A} can produce a back voltage opposing V_{21} and reducing V_{46}. Winding N_{C2} however, tends to drive core 2 further into saturation and therefore can produce no flux change in core 2, and consequently no voltage in winding N_{L2B} tending to aid V_{21}.

During the set half-cycle, the voltage V_{64} is normally only slightly positive because the rectifier is conducting in the positive direction. However, with an alternating control voltage sufficiently large to cause a reduction in output voltage, it is noted experimentally (as in Fig. 5(D)) that point 4 becomes positive with respect to point 6 during the set half-cycle. This potential difference can exist because of the high reverse resistance of the rectifier. The fact that V_{16} can and does exceed V_{14} during the set half-cycle plays an important part in explaining output drop-off in the following section.

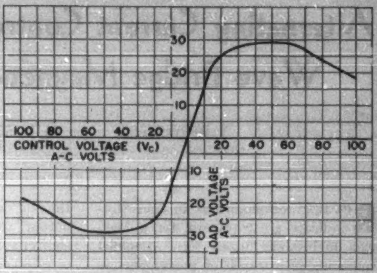

Fig. 2. Transfer characteristic with alternating voltage control

Source Current

The voltage across R_S, V_{31}, is important since it can also be used to determine the firing angle of each core. Fig. 6 shows this voltage when the motor load is used. This voltage represents the current obtained from V_S. Fig. 6(A) is the quiescent condition where the current rises sharply as both cores saturate during the set half-cycle. With a small control signal, Fig. 6(B) shows the sharp increase of current when core 2 saturates, and also the second sharp increase when core 1 saturates and shunts the load. For the maximum output, the wave shape of the current is that of Fig. 6(C). With excessive control signal, the wave shape of Fig. 6(D) is obtained. Fig. 6(D) shows that core 1 now saturates earlier during the set half-cycle and thus reduces output.

Load Voltage

Fig. 7(A) is the timing wave and represents a 115-volt rms, 400-cps (cycle-per-second) wave. Figs. 7(B), 7(C), and 7(D) show the output voltage V_{64} across the motor load for the conditions of output before maximum, at maximum, and after maximum output respectively.

Reduced Output With Large Alternating Control Voltage

The foregoing descriptions of wave forms reveal that output drop-off with large control signals of the phase shown in Fig. 1, occurs because of the earlier saturation of core 1, the second core to saturate. For an understanding of the problem it is necessary to determine why core 1 saturates before the end of the set half-cycle.

For the control signal phase relationship shown in Fig. 1, the control signal tends to oppose the saturation of core 1 on the reset half-cycle. The control signal tends to aid the saturation of core 1 on the set half-cycle. Consequently the early saturation of core 1 as a result of large alternating control voltage seems likely to be caused by some action of the control voltage during the set half-cycle. Experiments confirm this view; they show that if the control voltage is blocked by a rectifier during the set half-cycle, early saturation of core 1 and load voltage drop-off with a large control signal does not occur.

The problem of output drop-off with high alternating control voltage is now isolated. The drop-off occurs because the core which should stay desaturated during the entire set half-cycle saturates before the end of this half-cycle. This type of saturation results from the action of the control on the set half-cycle.

Cause of Early Saturation in Core 1

It has been shown that core 1 saturates as a result of control circuit action during the set half-cycle. Consequently, causes of this saturation are conveniently discussed in terms of the circuit of Fig. 8, which applies during that part of the set half-cycle after core 2 has saturated. This circuit is obtained from that of Fig. 1 by regarding both the saturated impedance of windings N_{L2A} and N_{L2B} and the forward resistance of their associated rectifiers as being negligibly small.

There is a net forward voltage across the load circuit rectifiers of core 1 as long as the supply voltage V_{L1} is greater than the load-winding induced voltage. If the induced voltage in the load winding becomes larger than V_{L1}, then the load-winding rectifier has reverse voltage applied and acts as an open circuit. Thus, when the load-winding rectifier can conduct, the load-winding determines the flux change on the set half-cycle. When current in the load winding is blocked, the control windings determine the flux change. Until the control voltage V_{C1} becomes sufficiently large to induce a voltage in the load windings of core 1 greater than V_{L1}, the voltage V_{L1} determines the flux change in core 1 on the set

D—After drop-off, with excessive control signal

half-cycle. This flux change is not sufficient to bring the core to saturation. When the voltage induced in the load windings N_{L1A} and N_{L1B} becomes greater than V_{L1}, there is reverse voltage on the load-winding rectifiers, and the control voltage determines the flux change. This flux change is now greater than that due to V_{L1}, and core 1 can be driven into saturation earlier than it would be with V_{L1} acting alone. The occurrence of the reverse rectifier voltage for large control signal during the set half-cycle is shown in Fig. 5(D).

Prevention of Output Drop-Off

Thus far, the effect of the reset winding in determining the load voltage drop-off has been ignored. These windings usually have fewer turns than the control windings so that the input impedance looking into the control windings is maximized.[2] Consequently the control voltage produces insufficient voltage in the reset winding to overcome V_{L1} and cause reset current during the set half-cycle.

It is now suggested that by adjusting the reset circuit, the control voltage can be made to cause reset current before this voltage can cause the load rectifiers to block. In this case, the reflected current in the control circuit will cause a voltage drop in R_C acting to limit V_{C1} and prevent load voltage drop-off. One method of achieving the desired reset circuit behavior is to supply the reset circuit from a separate and lower voltage source and then reduce the reset resistors as necessary to maintain the original reset action. This, however, reduces both input impedance and gain.[3] Similar disadvantages apply if the limiting is achieved by increasing the number of reset winding turns. It seems most practical to prevent drop-off by inserting a limiter circuit in the preamplifier.

Determination of Firing Angles

In the design of an output stage, the primary objective is to obtain maximum useful output with a minimum of apparatus. Considerations of output to input power ratio are usually secondary as long as the input power requirement is not excessive. Particularly in the case of a motor load, a knowledge of the relationship between firing angles of the two cores is desirable in order to achieve a combination of circuit parameters yielding firing angles which will provide a maximum fundamental component in the harmonically rich output voltage supplied to the motor.

Determination of First Firing Angle

As shown in Fig. 1, the polarity of V_C is such that during the reset half-cycle (point 3 negative) the flux in core 2 is increased relative to the flux in core 1. Core 2 will then fire first, at some angle θ_2, determined by the difference $\Delta\phi_2$ between its flux level at the beginning of the set half-cycle and the flux level for saturation. It follows that the maximum change in flux linkages which can occur with an N_L-turn loading winding on core 2 in the time interval between $t = 0$ (the beginning of the set half-cycle) and $t = t_2$ (the time at which core 2 saturates) is $N_L\Delta\phi_2$. This fixes the time t_2 in accordance with equation 1.

$$N_L\Delta\phi_2 = \int_0^{t_2} e_2\,dt \tag{1}$$

During the interval $0<t<t_2$, $e_2 = {}^1/_2\, v_s$. If the time phase angle at time t is defined as $\theta = wt$; then

$$N_L\Delta\phi_2 = \frac{1}{2w}\int_0^{\theta_2} |V_S|\sqrt{2}\sin\theta\, d\theta \tag{2}$$

To solve for θ_2, the angle at which core 2 fires

$$N_L\Delta\phi_2 = \frac{|V_S|}{\sqrt{2}w}(1-\cos\theta_2) \tag{3}$$

and

$$\cos\theta_2 = 1 - \frac{\sqrt{2}wN_L\Delta\phi_2}{|V_S|} \tag{4}$$

Determination of Second Firing Angle

In determining the second firing angle, it is convenient to define the difference between the flux levels existing in the two cores during the interval $0<t<t_2$ as $\Delta\phi_d$. This difference can be expressed in terms of the quiescent firing angle θ_q corresponding to zero control signal, and the angle θ_2. To advance the firing of core 2 from θ_q to θ_2, its flux level must be increased by ${}^1/_2\Delta\phi_d$ since the control signal produces equal but opposite flux change in the other core. Thus, following the same method used to obtain equation 2

$$\frac{1}{2}N_L\Delta\phi_d = \frac{1}{2w}\int_{\theta_2}^{\theta_q} |V_S|\sqrt{2}\sin\theta\, d\theta \tag{5}$$

and

$$N_L\Delta\phi_d = \frac{|V_S|}{w}\sqrt{2}(\cos\theta_2 - \cos\theta_q) \tag{6}$$

Equation 6 specifies the change in flux linkage which can take place in one load winding of core 1 between the angle θ_2, at which core 2 saturates, and the angle θ_1, at which core 1 saturates. Equating the integral of e_1 during the interval $\theta_2<\theta<\theta_1$ to this change in flux linkage.

$$V_S|\sqrt{2}(\cos\theta_2 - \cos\theta_q) = \int_{\theta_2}^{\theta_1} e_1\, d\theta \tag{7}$$

Thus the second firing angle can be obtained by solving equation 7 for θ_1.

The voltage e_1 is that which is induced in one load winding on core 1, and its mode of variation during the interval $\theta_2<\theta<\theta_1$ can be determined from the circuit shown in Fig. 8.

The circuit of Fig. 8 neglects the combined effect of forward resistance in the load rectifiers and resistance in the load windings of the saturated core (core 2). In this case $e_1 = v_{L1}$. Suitable resistors can be added to the circuit of Fig. 8 to represent the forward resistance of the rectifiers and the saturated resistance of the windings of core 2.[3]

Analogue Computation of Second Firing Angle

Manual calculation of θ_1 from equation 7 is tedious for any but the simplest types of load, whereas the use of an a-c network calculator greatly facilitates the plotting of many sets of characteristics showing θ_1 as a function of θ_2 for a wide range of circuit parameters and values of θ_q. A method for using a network calculator to solve for θ_1 is given in Appendix II.

Curves so obtained to relate θ_1 to θ_2 for various values of load shunt capacitance with a typical load are shown in Fig. 9. Note the action of the capacitance in delaying the firing angle of core

Vol.
Pt. 1
1956

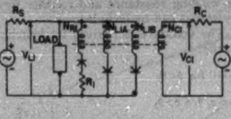

Fig. 8. Magnetic amplifier circuit when core 2 is saturated ($\theta>\theta_2$). Winding resistance and forward resistance of load rectifiers considered negligible

1. R_S was held at 100-ohm resistance throughout the analogue computations. The frequency of all voltages was 440-cps, hence the whole circuit was similar to that actually used with the magnetic amplifier of Appendix I.

While the method is inherently accurate, extreme accuracy was not attempted in obtaining these curves because of the lack of an accurate synchronous switch. Indicated values of θ_1 are probably within 4 degrees of their true value in most cases. The results presented here are in the nature of an illustration of the method of analysis and a qualitative comparison of the effects of various changes in the load impedance.

Manual Calculation of Second Firing Angle

Test results, Figs. 4(A) through 4(C), show that with the resistance load used, the second firing angle θ_1 changes only slightly from its quiescent value as the control signal is increased. This observation led to an investigation of the effect of load resistance on firing angles. The firing angle of the late-firing core 1, is related to the proportion of supply voltage applied to the load winding of core 1 after core 2 fires.

If K is the constant factor by which e_1 is increased after θ_2, then

$$e_1=\frac{K\sqrt{2}|V_S|}{2}\sin\theta \text{ for } \theta_2<\theta<\theta_1 \qquad (8)$$

The limits of K are $0<K<2$ as R_L varies from $0<R_L<\infty$. When $R_L=R_S$, then $K=1$ since both before and after the firing of core 2, core 1 will have the same voltage impressed.

From equation 7

$$|V_S|\sqrt{2}(\cos\theta_2-\cos\theta_q)=\int_{\theta_2}^{\theta_1}\frac{K\sqrt{2}|V_S|}{2}\sin\theta\, d\theta \qquad (9)$$

This equation agrees with Woodson's[3] equation F5. Solving now for θ_1

$$(\cos\theta_2-\cos\theta_q)=\frac{K}{2}(\cos\theta_2-\cos\theta_1) \qquad (10)$$

and

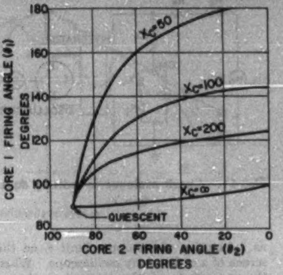

Fig. 9. Relationships between θ_1 and θ_2 for various values of X_C as determined from analogue computations ($R_S=100$, $R_L=150$, $X_L=150$), $\theta_q=90$ degrees

$$\cos\theta_1=\left(1-\frac{2}{K}\right)\cos\theta_2+\frac{2}{K}\cos\theta_q \qquad (11)$$

When K is less than unity, the equation is meaningful only for the values of θ_2 larger than that corresponding to $\theta_1=\pi$. For smaller values of θ_2, core 1 does not saturate, and a second firing angle θ_1 does not exist.

Equation 11 may be used to obtain the curves shown in Fig. 10 for various values of K. These curves show that as the load resistance becomes greater than the source resistance, K becoming larger, the control voltage loses control of the firing angle of the late-firing core.

Conclusions

The use of alternating voltage to control the half-wave bridge magnetic amplifier requires special precautions to avoid reduced output as a result of large control signals. The reduced output is caused by excessive voltage in the windings of the late-firing core during the set half-cycle.

This excessive voltage produces earlier firing of the core. Normally, the voltage impressed on the load windings of the late-firing core determines flux change on the set half-cycle and consequently the firing of the core. With large control signals, the control-winding voltage determines the flux change in the core as evidenced by a back voltage on two of the load winding rectifiers during the set half-cycle. The greater flux change as a result of the larger control signal then causes earlier firing of the core with a resulting reduction in output.

Limiting in the preamplifier is the most immediate solution to the problem of output reduction, although compromise design of the reset circuit holds further possibilities.

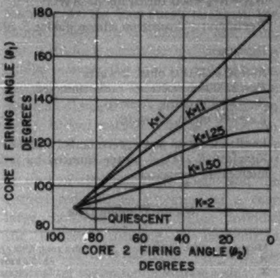

Fig. 10. Relationships between θ_1 and θ_2 for resistive load as calculated from equation 11

Test results with a resistance load show that under certain conditions of load the control voltage cannot control the firing angle of the late-firing core. Analysis shows that when the source and load resistance are equal, the control voltage has complete control of the firing angles of both cores. When the load resistance becomes greater than the source resistance the control voltage begins to lose control over the firing angle of the late-firing core. As the load resistance becomes much greater than the source resistance, the firing angle of the late-firing core tends to stay at its quiescent value even with increased control voltage.

The a-c network calculator can be used to determine the relationship between firing angles for any desired load condition. It is expected that the network calculator will find extended use not only in determining firing angles, but also in the choice of circuit elements by providing a more direct indication of the fundamental component of output voltage.

Appendix I. Design Details for Test Magnetic Amplifier

For the circuit of Fig. 1, the following listed components were used:

Excitation (V_S): 115 volts rms, 400 cps.

Core: Arnold Engineering Company *4635-D2* Deltamax toroid.

Core dimensions in inches:

Outside diameter, 1.375.
Inside diameter, 1.00.
Width, 0.25.
Tape thickness, 0.002.

Windings:

$N_{L1A}=N_{L1B}=N_{L2A}=N_{L2B}=1{,}300$ turns, no. 32 AWG (American Wire Gauge) wire
$N_{R1}=N_{R2}=500$ turns, no. 33 AWG

$N_{C1} = N_{C2} = 400$ turns, no. 33 AWG

Rectifiers: Transitron silicon diodes *S-201*.

Resistors:

$R_1 = R_2 = 27{,}000$ ohm, 2 watts
$R_3 = 2{,}000$-ohm 2-watt potentiometer
$R_C = 10{,}000$ ohms, 2 watts

Appendix II. Method of Using A-C Network Calculator in Determining Second Firing Angle

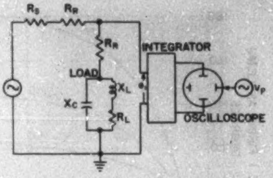

Fig. 11. Circuit analogue for solving equation 7

The upper limit of the integral given in equation 7 can be determined for given values of θ_q and θ_2 by displaying this integral as a function of its upper limit θ_1 on the screen of a cathode-ray oscilloscope. When the magnitude of the integral reaches a value predetermined in equation 7 for given values of θ_q and θ_2, the particular value of θ_1 corresponding to the given data is read from the oscilloscope.

The circuitry used in developing the required voltage integral, and a null method of reading the time phase angle θ_1 is illustrated in Fig. 11, which is a revision of Fig. 8 showing a switched alternating voltage applied to a circuit containing the R_S and load elements. In addition, two elements R_R have been added. If these are each made equal to the sum of the resistance of one "saturated" winding and the forward resistance of one load rectifier, the effects of winding resistance and rectifier forward resistance can be included.

The voltage v_t is derived by switching v_s so that

$v_t = 0$ for $\theta < \theta_2$

$v_t = v_s$ for $\theta > \theta_2$

The integrator and the vertical deflection system of the oscilloscope are calibrated by using v_s in place of e_1 at the integrator input and observing the peak to peak deflection of the oscilloscope trace. Phase calibrations are made with the use of a separate generator whose output voltage v_p can be phase-shifted relative to v_s by means of a calibrated phase dial. All phase angles can then be read on the phase dial by using it to move the oscilloscope trace horizontally to a predetermined null position.

Microwave Facilities with Built-In Reliability

R. G. KUCK
NONMEMBER AIEE

THIS PAPER describes a short-haul microwave radio system now providing toll quality telephone message service between San Diego (elevation 320 feet), Calif., and the Laguna Mountain recreation area (elevation 6100 feet), Calif. The microwave portion of the system employs Motorola frequency diversity equipment operating in the 5,925 to 6,425 mc (megacycle) common carrier allocation. The microwave system is presently multiplexed with 28 channels of Lenkurt *45 BX* carrier telephone channelizing equipment.

This system has been engineered so that it can be extended as required. Such an extension to the community of Borrego in the Imperial Valley is scheduled for completion in the second half of this year. At that time, a community dial office will be served exclusively by microwave facilities; Fig. 1.

The flexibility provided by such a combination of microwave and carrier equipments can be readily observed in that the original system will carry both the 28 channels to Mt. Laguna, and also the additional requirement of 12 channels to Borrego.

Initial Planning

The large increase in requirements between San Diego and Laguna Mountain, together with the lack of an existing readily expandable facility, opened the way for a primary relief study. Various combinations of cable and open-wire carrier systems as well as microwave radio were considered. The existing route consisted mainly of an open-wire lead which past experience had shown to be vulnerable to the high winds and sleet conditions in the Laguna Mountain area. A cable route along the existing wire lead would no doubt provide increased reliability as compared to the existing wire. However, in order to provide for this increased reliability, considerable pole line rearrangements would be necessary. Such rearrangements are entirely practical, but the charges for construction in the rugged mountain country would be high and no real diversification of routing would result.

The air-line distance between San Diego and Laguna Mountain is 44 miles, and a profile of this path is shown in Fig. 2. As may be seen, the controlling intermediate terrain features are located 31 and 41 miles respectively east of San Diego. Under varying conditions of the refractive index of the atmosphere, either of these points could present a serious obstacle to microwave propagation. Further field studies were undertaken to verify the information taken from the U. S. Geological Service maps. Following the map study height-loss testing equipment was employed to assist in determining the clearance required above the intermediate terrain features which might adversely affect microwave propagation on this path. By conducting height-loss

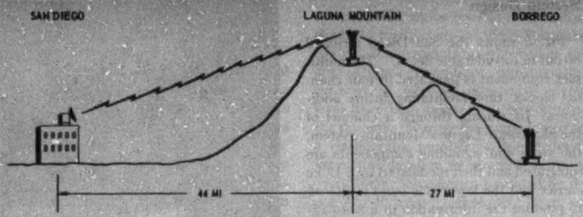

Fig. 1. Pictorial of microwave system

test transmissions, it was possible to verify data previously obtained from line-of-sight tests using the usual light-flashing techniques. From these field and office studies a tower height of 108 feet was selected. With this tower height the center of the reflector is 104 feet above mean ground level.

It might be surprising to discover that a site location in southern California would be subject to extreme weather conditions. When the moisture-laden air flowing across the San Diego lowlands rises to the cooler mountain areas, high winds and serious icing conditions often result. Recognizing these extreme weather conditions led to designing the tower, guys, anchors, and reflector as shown in Fig. 3, to withstand actual wind loads in excess of 100 miles per hour, and one inch of radial ice. The tower design also contemplated the additional load of a second reflector which would facilitate extension of the system to other locations as future requirements should dictate.

Terminal Design

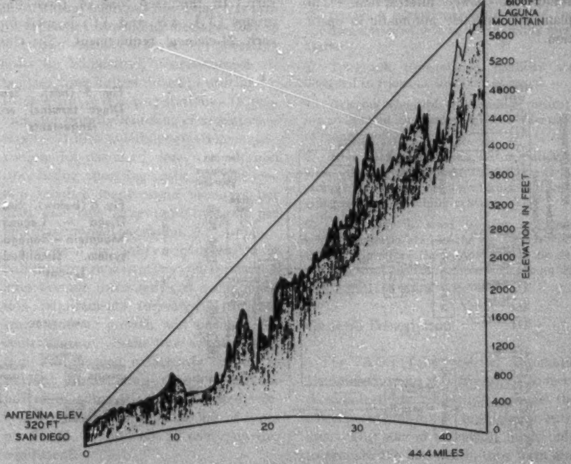
The San Diego terminal consists of 28 channels of Lenkurt *45 BX* carrier telephone equipment applied to the base band of the Motorola microwave equipment. At this terminal, remote type of microwave equipment was selected, thereby allowing for the installation of the carrier and microwave remote control bays on a lower floor of the office, with the installation of the radio-frequency and intermediate frequency portions of the microwave in a weatherproof cabinet on the roof of the building; see Fig. 4. All necessary tuning adjustments can be remotely actuated from the control unit located within the office. In this manner, wave guide runs are reduced to a minimum.

In consideration of the path length involved, the low power output (0.1 watt), and the possibility of severe fading as experienced on other microwave paths in this locale, three precautionary measures were employed to insure the desired reliability. This installation as previously noted is arranged for frequency diversity operation, i.e., two transmitters operating on different frequencies are simultaneously energized. The advantage gained by this technique arises from the small time differential normally existing between the times when a given fade crosses two adequately separated frequencies in a band. By means of proper control circuits at the receiving terminal, the base band signal as derived, can be taken from either receiver, depending upon the instantaneous received signal level. An automatic selection circuit using the information gained from the intermediate frequency limiters, together with a fail-safe trigger derived from a pilot receiver, accomplishes the required switching.

The second precautionary measure employed involves the use of high-gain antennas. At the San Diego terminal, the choice, based on availability and cost, was a 10-foot parabolic antenna. In a similar manner, the antenna design chosen for the mountain location consists of a 40-inch diameter parabola feeding an 8- by 12-foot curved reflector. The operation of this system may be better understood if the parabola is thought of as part of the feed mechanism, and the curved reflector as a section of a very large parabola. The reflector provides the ultimate focusing of transmitted energy and it is therefore the principle control on the antenna system gain.

The third means of providing system margin consisted of the installation of compandors on all voice circuits. The Lenkurt *45 BX* equipment has a compandor option and the additional cost associated with this option was thought to be justified for this application. Although, no appreciable increase in fading margin results from the use of compandors, a very noticeable decrease in the channel noise level for a given fade depth does result. This decrease in channel noise exists only when the received signal (prior to detection) is considerably above noise level. When this signal-to-noise ratio of a frequency modulated system approaches low values, the system rapidly degrades, and the compandor no longer provides its normally available quieting effect. Compandors, however, by allowing noise to come through only in the presence of speech and not during inter-

Fig. 2. San Diego–Laguna Mountain profile



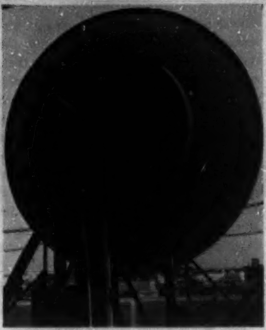


Fig. 3. San Diego, equipment cabinet and antenna

vals between syllables and words, reduce the disturbing effects on a voice channel when high background noise levels exist.

With one exception, the terminal installation on Laguna Mountain is similar to that at San Diego, already discussed. The radio equipment is of the micropackage variety, i.e., it is completely self-contained with the parabolic antenna located atop the equipment bay and pointed through a skylight at a reflector. In this instance, the skylight is specially designed to pass microwave energy with negligible impairment. By this means, the distance between the radio-frequency bay and the parabola feed is held to one foot or so. At this location, an emergency gasoline powered electric plant was installed to bridge the period of commercial power interruption. This plant is completely automatic in operation.

System Design

Fig. 5 shows the San Diego terminal layout in considerable detail. The multiplex equipment is packaged in four channel blocks, thus facilitating future additions. In tracing through a channel of the San Diego–Laguna Mountain system, the voice and signalling components are integrated and then modulated by a 12-kc carrier and the lower side band is filtered to produce the information in a 8- to 12-kc bandwidth. In similar manner, channels 2, 3, and 4 are modulated around 16, 20, and 24 kc respectively, to produce a total of four channels in the frequency spectrum of 8 to 24 kc.

In the pregroup unit, the first four channels are combined and modulated with a 96-kc carrier to produce a lower side band extending from 72 to 88 kc. In a similar manner, two other pregroup units employing modulating frequencies of 80 and 64 kc respectively produce lower side bands extending from 40 to 72 kc. At this point, 12 circuits have been modulated into the 40- to 88-kc range.

The informational energy now contained in the 40- to 88-kc band is sent through a base group unit where depending upon whether group 1 or 2 equipments are provided, a 40- to 88-kc or a 92- to 140-kc band containing 12 channels is generated. When the full complement of channel and pregroup units has been employed, a complete 24-channel group results, occupying a frequency spectrum from 40 to 140 kc.

Where the circuit requirement to be satisfied is 72 channels or less, only one additional step of modulation is necessary. In this step, one of three line groups (*XA*, *XB*, and *XC*) is used for each 24-channel requirement. By this means the 24 channel groups are stacked in one of the following allocations: *XA*, 40 to 140 kc; *XB*, 164 to 264 kc; and *XC*, 344 to 444 kc.

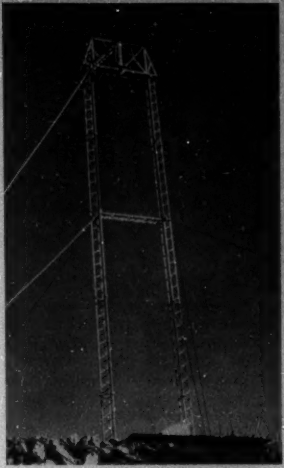

Fig. 4. Laguna Mountain, tower and reflector mounting

The total of the allocations shown is coupled into the base band or video amplifiers of the two Motorola diversity transmitters. The output of each base band amplifier, in turn, modulates the repeller of the klystron microwave output stage. The radio frequency wave thus generated is composed of a frequency-modulated carrier operating in the 6,000 mc range.

At the receiving terminal, the incoming 6,000-mc carriers are demodulated to 70 mc in two receivers and then in turn demodulated to the video or base band frequencies. By means of a comparator circuit the outputs of the receivers are compared on the basis of the better operational signal and, by means of series of coaxial relays, the desirable one is selected. By a process which is the reverse of that previously discussed, the individual channels are derived.

Operation

Fig. 6 illustrates a simplified equipment layout from the San Diego terminal through the Mt. Laguna repeater to the Borrego terminal. A total of 40 circuits is now required, 28 terminating at Laguna Mountain and 12 extended to Borrego. The carrier equipment provided readily allows for augmentation to care for requirements which may be anticipated in the future.

The first section of the system was placed in service in March 1955. Initial system performance tests showed that all channels easily met the Bell Telephone System requirements for short-haul toll applications. In addition, continuous recordings of received microwave carrier level have been taken from last April to the present. During the summer months a considerable number of deep fades of very short duration were recorded. However, due to the margins provided by the use of diversity techniques, large antennas, and compandors as previously discussed, no noticeable system degradation was observed during this period.

Conclusions

Short-haul microwave systems (as contrasted with large-capacity transcontinental equipments) provide the design engineer with another very useful communications tool. In most instances, diversification of facility and routing, flexibility, and provision for future growth, together with immediate cost economies result from the use of microwave. Such systems properly designed and installed provide reliability comparable with other types of communication facilities.

Automatic Dispatch System for Half-Duplex Teletypewriter Lines

J. L. MAXWELL
ASSOCIATE MEMBER AIEE

H. K. FARRAR
MEMBER AIEE

HALF-DUPLEX multistation teletypewriter lines efficiently meet the needs of several points that require record communication with each other. In such cases it is important to be able to send messages to selected stations only. This ability is necessary to save paper, to provide privacy, and to avoid the need to scan all messages at each station to find those addressed to it. Direct interstation communication avoids sending all messages to a relay center for retransmission to other stations. This saves line and attendant time. To facilitate sending messages to addressee stations only, manually operated selective calling devices have been used. By present standards these are relatively slow. In addition, until recently it was necessary for attendants to initiate transmission of messages only when the line was idle. On a busy line this frequently required waiting for the line to become idle as shown by a line lamp. The attendant could then seize the line, operate the selecting equipment, and send the message. Sometimes attendants at two or more stations attempted to seize the line simultaneously. Unsuccessful attendants, unfortunately, had to resume waiting. On a busy line this procedure required appreciable amounts of nonproductive line and attendant time. Furthermore, there was no way to give an urgent message priority over other messages.

Automatic operation as described here greatly increases efficiency of half-duplex multistation teletypewriter lines. It provides privacy by sending messages only to addressee stations. It reduces operating costs by eliminating nonproductive attendant time hitherto used in waiting for the line and in selecting stations. It provides for priority handling of urgent messages. It also avoids contention among stations for use of the line. In addition to reducing operating costs, the new system handles many more messages per hour and can serve more stations per line than manual operation.

The need for automatic operation of half-duplex multistation teletypewriter lines became more acute as communication requirements increased with general economic growth and business decentralization. Some time ago the situation was deemed sufficiently urgent to warrant undertaking design work for providing automatic medium-sized teletypewriter services with the use of types no. *14*, no. *15*, and no. *19* teletypewriter equipment.

Basic Objectives

The following objectives were to be met.

The system should be automatic in:

1. Allowing all stations access to the line in specified sequence.
2. Permitting heavy-usage stations more frequent access to the circuit.
3. Directing messages only to addressee stations.

Centralized control should be provided.

Selection of stations should be by means of the standard teletypewriter 5-unit code for the following reasons:

1. Messages could be directed by station codes perforated in message tapes. This would permit use of the teletypewriter transmitter for sending station-selecting codes as well as messages.
2. Economies could be obtained by using the receiving teletypewriter as part of the selecting device as well as for receiving messages.
3. Telegraph transmission facilities are designed to transmit this type of signal.
4. Existing telegraph transmission measuring equipment and techniques could be used in maintenance.
5. It is adaptable to automatic switching with the reperforator-transmitter as a storage device between incoming and outgoing lines at switching centers.
6. This code is used by the sequence selector incorporated in the no. *28* teletypewriter; therefore the equipment to be developed would be compatible with the no. *28* line of teletypewriter equipment.

General Description

The TADS (Teletypewriter Automatic Dispatch System) was developed to meet these objectives. It greatly increases the efficiency of half-duplex multistation services. The station attendant needs only to prepare the message in tape form and

Paper 56-646, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 26, 1956; made available for printing April 17, 1956.

J. L. MAXWELL and H. K. FARRAR are with The Pacific Telephone & Telegraph Company, San Francisco, Calif.

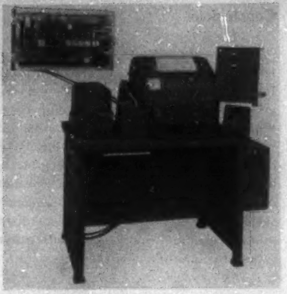

Fig. 1. Master station, controller cover removed

insert it in the transmitter of the teletypewriter, whether or not the line is busy. The TADS equipment starts the transmitters in sequence and directs the messages to the station or stations whose codes are perforated in the tapes or whose selecting buttons are depressed.

The basic TAD system consists of an automatic transmitter-start unit or controller located at a master station and a teletypewriter selector associated with each teletypewriter. The teletypewriters at all sending locations are equipped with perforators for tape preparation and with transmitters for automatic tape transmission.

Fig. 1 shows the master station teletypewriter with the station selector mounted on the right end of the table and the controller in a separate cabinet.

Twenty letters of the alphabet are suitable for station codes. V, M, O, and T are excluded as they can be generated by accidental opening and closing of the line. H and S are used for other functions. The same station codes are used to select stations and to start transmitters. The codes are used in lower case for station selection and in upper case for transmitter-start.

When 2-digit station codes are used, only two letters can be used as first digits on any one line. For example, X and Y might be used as first digits. In this case one group of 18 stations would have X for the first digit and a second group of 18 would have Y. This permits assigning 36 stations on one line.

The flexibility of the TAD system permits variations in arrangements to meet widely different customer requirements. This paper describes only the basic features.

Operation

Station codes are sent to all stations in sequence to start their transmitters if tapes have been placed in them. Stations which are not waiting to transmit respond to start codes with a no-tape signal (letter O). Thus each station in operating condition responds, either with transmission where tape is available or with a no-tape signal where there is no tape in the transmitter. This provides circuit assurance.

The search for waiting tapes proceeds as follows: Following a momentary idle line condition, the controller opens the line for about one second. This connects all machines to the line and starts their motors. The controller then sends the figures-shift code shifting all machines to upper case. This closes a set of contacts preparing each selector to respond to its transmitter-start code. The controller then sends the code for the first station in the sequence. If tape is available at this station, the transmitter starts. If no tape is available, the station sends the no-tape signal to indicate that the line and station are in working order. The controller then sends the start code for the next station. Should a station fail to respond with a no-tape signal or a message, the controller sends the start code a second time and, failing to get a response, he operates visual as well as audible alarms at the master station.

The operation of a SKIP key at the master station will retire the alarm, arrange to intercept messages for the station failing to respond, and cause the search to be resumed. Messages for that station will now be received on an intercept typing reperforator. The controller will continue to send the start code for this station in sequence but will not wait for a response before passing to the next. Continuing to send the code for a station on SKIP permits that station to send a message to notify the master station when service is restored. The SKIP key can then be restored to normal. The intercept arrangement will be described later.

Any combination of stations may be selected by including their codes in the tape. Each station can be equipped for one group or broadcast code. Any number of messages may be included in a single continuous tape, provided the proper format is used for each message. The transmitter will stop at the end of each message. The controller then sends the next start code. The transmitter stopped with messages remaining in its tape will restart and send the next message when it receives its start code in the next search cycle. This prevents one station from using the line for protracted periods. The equipment can be arranged to start designated stations more often than other stations if it is so desired.

The system has a normal capacity of 20 stations per line using single-digit codes, and a capacity of 36 stations per line using 2-digit codes. Transmission is limited to 60 or 75 words per minute at this time.

Station Selector

The station selector is housed in a cabinet mounted on the right end of the teletypewriter table; see Fig. 1. The equipment consists of relays, keys, lamps, and a cold-cathode-tube timing circuit. It is mounted on a gate which may be swung out to give access to the rear for maintenance or removed to facil-

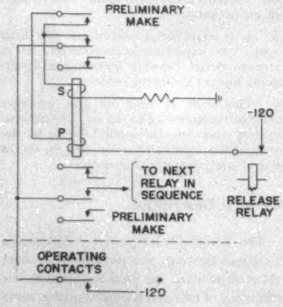

Fig. 2. Two-step relay circuit

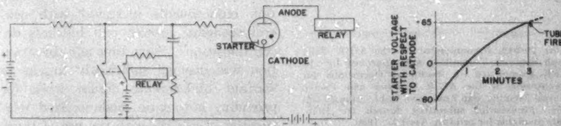

Fig. 3. Cold-cathode-tube timing circuit using battery reversal on capacitor

itate wiring. Components performing more than one function and special mounting arrangements have been utilized to reduce space requirements. D-c 120-volt power is obtained from the teletypewriter rectifier. The demountable line relay in the teletypewriter serves both the selector and the line magnets of the machine. The priority bid, circuit-assurance, and break signals for starting stations under manual operation are all generated by the same signal generator using different voltage, resistance, and capacitance values with a common polar relay.

Two-step relays have been used in some cases to make one relay do the work of two. An example of this technique is shown in Fig. 2.

Varistors are used in the circuit for two purposes:

1. To isolate operating paths, particularly those connected in multiple from a single contact in the typing unit.
2. To increase the release time of relays without affecting their operation. In this application the varistor is connected across the relay winding to present a high resistance to the operate potential and a low resistance to the voltage generated by the collapsing field.

Six special contact assemblies have been added to the typing unit to obtain the necessary functions for selective calling. A 3-element cold-cathode-tube timing circuit is provided to turn the station off one second after end of transmission. This operation may also be made dependent upon both end-of-transmission and end-of-message code. Making this operation dependent on end of transmission only has the advantage of automatically restoring the circuit assurance feature should the end-of-message code be omitted.

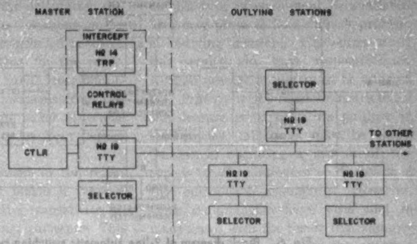
Three motor control options are available:

1. The motor turns on every time the station is connected to the line and turns off every time it is disconnected.
2. The motor normally stays on whenever the circuit is busy, regardless of whether or not the station has been selected. The motor automatically turns off whenever the circuit is idle for 15 seconds or more.
3. The motor runs continuously during service hours.

An audible alarm is activated and the transmitter stops when:

1. A tape snarl lifts the tape stop lever.
2. The end-of-address code is inserted in the tape ahead of the station selecting codes.
3. The code of the sending station has been omitted.

Fig. 4. Block diagram of TAD system with intercept equipment



After any of these events, the controller resumes searching after a momentary pause and searches the succeeding stations in sequence. Whenever the station where the fault has occurred is subsequently searched, it responds with a no-tape signal until such time as the tape is reset. The audible alarm can be retired only by removing the tape from the transmitter.

Should the controller be at rest after having made a complete search without finding a tape waiting, the busy lamp will be dark at all stations. During this condition, any transmitter can be started, without waiting for the automatic start, by operating the control key.

Such operation is recommended only in emergencies or in the event that the controller is not functioning. Otherwise, contention among stations may result and the advantage of automatic operation be lost.

Priority

Any station may send a priority message by the insertion of a tape in the transmitter and momentarily operating a key provided for this purpose. This causes a priority relay in the selector to operate and lock to the tape-stop contacts of the transmitter, which prepares the station to make a priority bid after the next end-of-message code.

Should the circuit be busy, the priority message will be the next transmitted. One nonpriority message may be transmitted ahead of the priority message if the controller is searching or the circuit is idle when a priority key is operated. In either case the following action takes place following the next end-of-message code:

1. The controller opens the line for the usual interval preceding the search. This causes the tape-withhold relays to be held operated through the marking contacts of the line relays at all stations. But at the station where the priority key was operated, a parallel holding circuit is provided for this relay through contacts of the priority relay.
2. The priority station (where the priority key was operated) opens the line a second time, releasing the tape-withhold relay at all other stations. This prepares the selectors at nonpriority stations to respond to start codes with no-tape signals even though tapes are available, which causes the nonpriority stations to be by-passed until the priority station has sent a message. Should the priority key be operated at more than one station the transmitter at the first such station in the search sequence will start. Following this transmission, the remaining such stations make a new priority bid without further attention. This arrangement permits separating the traffic into two classifications with very little loss of circuit time.

Controller

The controller is housed in an apparatus cabinet mounted on the wall or on a stand at the master station; Fig. 1. The components are mounted on a gate which swings out, giving access to the rear for maintenance. Components include relays, a 6-level-bank 22-terminal stepping switch, cold-cathode tubes, and associated resistors and capacitors. D-c 130-volt power is obtained from two

selenium rectifiers in the controller. Timing circuits, 2-step relays, and other devices similar to those in the selector are used in the controller.

The station codes are wired to five of the six stepping-switch levels for single-digit codes. In the case of 2-digit codes, the second digits only are wired to the bank.

The automatic transmitter-distributor of the teletypewriter at the master station serves to transmit both messages and start codes. This transmitter-distributor is equipped with auxiliary contacts operating from a cam on the lower end of the distributor shaft and with tape-withhold parts. Operation of the tape-withhold parts prevents stepping of tapes while start codes are being sent. Each time the brush arm of the distributor enters the start segment, the auxiliary contacts close to control the various stepping and transfer functions.

OPERATION

A relay at the master station follows all line signals. Upon closure of the line following transmission of a message this relay operates to its marking contact. This causes a positive charge to build up on the control anode of a cold-cathode tube in the associated timing circuit. The tube fires in about two seconds, opening the line. This releases a relay and lights the "busy" lamp at each station. It also starts a second timing circuit that after about one second closes the line, connects all machines to the line and starts the master station transmitter. The auxiliary contacts in the transmitter close at the beginning of the start pulse, connecting the distributor segments to relay circuits in the controller. Closure of the auxiliary contacts also causes the figures shift code to be transmitted. Closure of the auxiliary contacts on the next revolution causes the first character of the station code, for example, X, to be transmitted. This assumes the equipment is arranged for 2-digit calling and that X is the first digit of the first group. On the next revolution the distributor is connected to the stepping-switch bank and the second character in the station code is sent, for example, A, if station XA is to be started. In this case the 1 and 2 levels of the stepping-switch would be wired for marking and the 3, 4, and 5 levels for spacing. If a no-tape signal is returned indicating everything in order but no tape available, the X is again transmitted. The switch steps again, and the next station code, for example, B, is sent. Assuming tape is available, the transmitter starts and addressee stations are selected as a result of station codes in the tape. The controller now waits until end of transmission before sending the next station code.

At the end of one cycle, the stepping switch operates a relay which causes the first digit for the second group, for example, Y, to be transmitted at each step. Should a complete search be made of both the X and Y groups without starting a transmitter, the controller will shut down for a rest period of three minutes, six minutes, or for an indefinite period, as determined by a key at the master station. Should the controller be at rest it can be reactivated by operating a key at any station.

The cold-cathode-tube timing circuit includes an 18-microfarad capacitor and a 10-megohm resistor as shown in Fig. 3. To attain a 5-to-6 minute rest interval, the capacitor is charged in one direction while the line is busy and in the other during the rest interval. The timing interval following end-of-transmission therefore becomes the discharge time plus the charge time of the capacitor.

Intercept

Intercept equipment at each master station includes a typing reperforator, a station selector, control relays, and a panel equipped with a key and lamp for each station.

The typing reperforator receives messages with nonvalid station codes or incorrect format. Messages for stations temporarily out of service may also be intercepted.

A lamp lights on each step of the stepping switch in the controller indicating the progress of the search. Operation of the associated locking-type SKIP key causes the lamp to stay lit and the messages for that station to be received on the intercept typing reperforator. The start code for the station on SKIP is sent as before but the controller continues the search sequence even though no response is received.

Tapes received on the intercept reperforator can be retransmitted by means of the master station transmitter. Should incorrect station codes appear in the tape the correct codes can be perforated in a separate tape and the two spliced together. When push-button equipment is provided, it can be used to provide the correct codes without preparing a tape. Fig. 4 shows the TADS with intercept equipment.

Push-Button Selection

Push-button selecting equipment provides for sending station codes for any one or more of 20 stations, a reperforator for manual relaying, or a reperforator-transmitter for automatic retransmission to another line.

A key box equipped with key and lamp for each station, a common lamp, a start key, and a release key, is mounted on the left end of the table for a no. *19* teletypewriter. This adds about $2^1/_2$ inches to the over-all length of the machine.

Relay equipment for the push-button feature is housed in a 6-plate apparatus cabinet identical to that used for the controller. The basic push-button unit provides for eight codes. Provision is made for two additional units of seven codes each. The push-button equipment has the following limitations and operating features:

1. It is for use with single-digit station codes only.
2. There is a maximum of 20 station selecting codes.
3. It sends end-of-address codes after the station codes.
4. It sends end-of-message code if not in tape.
5. The transmitter can be loaded and station codes selected while the line is busy.

6. It permits proper direction of tapes with incorrect or garbled station codes. (The incorrect codes become part of the text.)

7. It permits sending tapes including proper station codes by simply operating the START key.

Push-button operation has advantages where:

1. Attendants cannot be depended upon to follow the prescribed message format.
2. Tapes without station codes are received over other facilities for introduction into a TAD system.
3. Messages with incorrect codes are received on an intercept reperforator and must be re-sent.

Typing Reperforator Control Circuit

This circuit facilitates the manual relaying of traffic between two circuits. Each circuit must be equipped at the relay point with a no. *19* teletypewriter, a selector, and a typing reperforator with its control circuit. The following requirement must be met:

No codes be punched in the tape that might interfere with directing the message on another circuit. The tape must be automatically fed out clear of the tape guide to permit it to be torn off without mutilating perforations needed for retransmission. The reperforator must resume operation without omitting a character, misprinting, or introducing an extraneous character in case it is selected for another message during feedout. This is accomplished by assigning a 2-digit code for the typing reperforator; for example RV. A letters-shift code following the letter V is inserted to allow time for the receiving cam of the reperforator to stop before a selecting or message character is received; see Fig. 5.

Automatic Cross-Office Switching Between Two Lines

Fig. 6 shows an arrangement for automatically relaying messages between two lines. Two reperforator-transmitters are required at the switching point, one for relaying in each direction. A teletypewriter and selector are also required here on each line. The switching point may be either at the master station or at an outlying station.

Messages are directed to the receiving side of a reperforator-transmitter by means of a station code. Receipt of the code connects the receiving side of the reperforator-transmitter to the line and disconnects the teletypewriter at that station. The message must, of course, include the codes for the destination stations on the other line. Stations on the originating line can be included provided their codes precede that for the reperforator-transmitter. Each reperforator-transmitter receives messages from one line and transmits them to the other line in response to start codes from the associated controller.

A flip-flop arrangement in the reperforator-control circuit makes it possible to have the reperforator-transmitter respond to alternate start patterns. This means that the transmitter can be started after each message or after alternate messages, whichever best meets traffic requirements. Preferential handling of priority messages is provided by use of a priority code that conditions the flip-flop circuit to start the reperforator-transmitter after each message. Should the outgoing line be idle, reception of a priority message by the reperforator-transmitter will cause a pulse to be sent to the line. This activates the controller which starts all machines and sends the figures-shift code causing the priority message to be transmitted.

Tape failure in the reperforator-transmitter will operate an audible alarm and automatically cause the teletypewriter to receive all cross-office messages.

Automatic cross-office relaying of messages extends the application of the TAD system making it feasible for as many as 72 stations (36 on each of two circuits) to exchange traffic automatically.

Conclusion

The widespread application of TADS equipment to half-duplex private-line teletypewriter services has emphasized the need for automation of moderately extensive services. Economies in attendance and paper usage and greatly increased circuit efficiency have resulted in demand for the system.

This type of service brings with it new maintenance problems for the serving communications company. Users frequently require stations at remote locations. This places more rigid requirements on line facilities which sometimes are open wire. Minor interruptions or irregularities which may pass unnoticed with manual operation may seriously interfere with an automatic system. An important requirement is that adequately trained maintenance people experienced on this type of equipment be available. This may prove to be a difficult problem in outlying districts. Customers using this service also have responsibilities. A rigid message format must be adhered to. Priority traffic must be restricted if this feature is to serve its purpose in emergencies. Messages must be short. Success in operating a system of this type is largely contingent on discipline of the customer's attendants. However, these requirements have been met in many cases with the result that the system described is meeting the exacting requirements of many customers.

Nomenclature

End-of-address code: A combination of characters or functions, normally carriage-return and line-feed, used between the station codes and the associated message text for disconnecting the nonselected stations.

End-of-message code: A combination of characters or functions, normally figures-shift and the letter H, used at the end of the message text to stop the sending transmitter and to cause the controller to resume the search.

Half-duplex line: A teletypewriter line capable of transmission in both directions but not simultaneously.

Mark: Closed circuit.

Master station: The station on a TAD system at which the automatic start unit (controller) is located. When intercept equipment is used it is also installed at the master station.

No. 19 teletypewriter: A page-copy teletypewriter, transmitter-distributor, and a tape perforator mounted on one table.

Perforator: A device for preparing a message in punched tape form for transmission by means of a transmitter-distributor (part of the no. 19 teletypewriter).

Reperforator-transmitter: A teletype machine consisting of a typing reperforator and automatic transmitter in one unit. Messages are received in the form of typed and punched tape and are automatically retransmitted. Separate control provides storage between the receiver and transmitter.

Space: Open circuit.

Transmitter-distributor: A device for automatic transmission of perforated tape on a teletypewriter circuit (part of the no. 19 teletypewriter).

Typing reperforator: A teletypewriter which receives messages from the line, types them on tape, and perforates the tape for retransmitting the messages.

The Analysis of Sampled Data Servomechanisms Performed on the IBM Type 650

B. M. TOSTANOSKI
ASSOCIATE MEMBER AIEE

Synopsis: Because of the need for more accurate and versatile control capabilities than can be obtained economically with continuous systems, discrete filters (digital computers) are being substituted as control elements in many applications. The exact response of linear systems which combine continuous and discrete filters can be obtained for discrete values of time by a series of well-defined mathematical processes. Since these processes require many computations of a repetitive nature to obtain complete response data, manual methods of computing are often not practicable and general-purpose digital computers such as the IBM (International Business Machines Corporation) type *650* are used to assist in the analysis of these systems.

A SAMPLED DATA control system is one in which the signal supplied to one or more parts of the system is delivered at discrete values of time. The types of sampled data systems which have attained importance in military and industrial control applications are those which use discrete filters (digital computers) as control elements to monitor the activity of continuous controlled members.

The response of a real linear system containing both continuous and discrete filters can be exactly defined at sampling instants by a difference equation having a finite number of terms. The constant coefficients for this difference equation are obtained directly from the discrete system transfer function. A discrete system transfer function is in turn obtained by mathematically substituting equivalent discrete filter transfer functions for continuous functions and then reducing the system representation to a ratio of polynomials in the discrete transform variable z.

System reduction and subsequent response evaluation require a large number of computations, even when simple systems are investigated. Therefore, general-purpose digital computers such as the IBM type *650* can be profitably applied to the solution of these problems.

The purpose of this paper is to discuss the development of computer programs which can be used to assist in obtaining fast and accurate solutions of linear sampled data systems. After the programs are discussed, some indication is given regarding their application to nonlinear sampled data systems and to continuous linear systems.

Filter Representation and System Reduction

In general, sampled data control systems combine both continuous and discrete filters. The linear continuous filter, Fig. 1(A), is defined by the differential equation

$$o(t)+B_1\frac{d}{dt}o(t)+B_2\frac{d^2}{dt^2}o(t)+\ldots+B_b\frac{d^b}{dt^b}o(t)$$
$$=A_0i(t)+A_1\frac{d}{dt}i(t)+A_2\frac{d^2}{dt^2}i(t)+\ldots+A_a\frac{d^a}{dt^a}i(t)\quad(1)$$

and by the transfer function

$$\frac{O(s)}{I(s)}=G(s)=\frac{\sum_{j=0}^{a}A_js^j}{1+\sum_{j=1}^{b}B_js^j}\quad(2)$$

The input to a continuous filter may be either a discrete or continuous function of time, whereas the output is always a continuous function.

The linear discrete filter, Fig. 1(B), is defined by the difference equation

$$o^*(t)+B_1o^*(t-T)+B_2o^*(t-2T)+\ldots+B_bo^*(t-bT)$$
$$=A_0i^*(t)+A_1i^*(t-T)+A_2i^*(t-2T)+\ldots+A_ai^*(t-aT)\quad(3)$$

and by the transfer function

$$\frac{O^*(s)}{I^*(s)}=W(\epsilon^{-sT})=\frac{\sum_{j=0}^{a}A_j\epsilon^{-jsT}}{1+\sum_{j=1}^{b}B_j\epsilon^{-jsT}}\quad(4)$$

where the asterisk is used to designate information which is in sampled form and T is the sampling period. Setting $\epsilon^{-sT}\equiv z$, equation 4 becomes

$$\frac{O^*(s)}{I^*(s)}=W(z)=\frac{\sum_{j=0}^{a}A_jz^j}{1+\sum_{j=1}^{b}B_jz^j}\quad(5)$$

The input and output of a discrete filter are discrete functions.

One of the simplest forms of a servomechanism which combines both types of filters is shown in Fig. 2(A). The continuous system input and the output of the controlled member are differenced to determine the system error. This error is sampled for processing within the discrete filter. The exact determination of the system response would require the inversion of transforms containing infinite series.[1] Truncating the series and then inverting yields a solution of the system response which is a continuous function of time. This method results in an approximate evaluation of the output for all values of time.

A more useful approximation of the system output can be obtained by mathematically reducing the entire system to an equivalent discrete filter described by a difference equation. This method results in an expression for the system output which is not continuous. However, the solution is exact at the sampling instants of time.

The mathematical technique by which discrete transfer functions are defined in terms of corresponding continuous functions[1] is applicable to the configuration shown in Fig. 3(A) when the input to the continuous filter is sampled data. The combination of a continuous filter followed by a sampler is reduced to an equivalent discrete filter, shown in Fig. 3(B).

For mathematical equivalence, if

$$G(s)=\frac{k_1}{s+a_1}+\frac{k_2}{s-a_2}+\ldots+\frac{k_n}{s-a_n}+\ldots+\quad(6)$$

then

$$\frac{O^*(s)}{I^*(s)}=G^*(s)=\frac{k_1}{1-\epsilon^{a_1T_s}}+\frac{k_2}{1-\epsilon^{a_2T_s}}+\ldots+\frac{k_n}{1-\epsilon^{a_nT_s}}+\ldots+\quad(7)$$

Summing the terms of equation 7 over a least common denominator will produce

Pt. 1
1956

a ratio of polynomials in s, having real coefficients, as in equation 5. When $G(s)$ contains multiple roots, the corresponding discrete equivalents can be described in an analogous manner.

By using the equivalence indicated by equations 6 and 7, a linear system can be totally represented in the domain of discrete filter operation. The over-all system transfer function can be reduced to the form of equation 5, which immediately defines the coefficients of the corresponding difference equation, equation 3. This method is apparent in the reduction procedure followed in Fig. 2.

The sampled output signal of Fig. 2(A) may be determined by first redrawing this figure as Fig. 2(B) in which the sequence of sampling and differencing is interchanged and the feedback path is redefined. The feedback path, having sampled input and output, is the equivalent of a discrete filter and can be represented as $G^*(s)$ by the method which resulted in equation 7. This reduction is incorporated in Fig. 2(C) which is obtained from the configuration of Fig. 2(B) by reducing the loop and adding a mathematical sampler after the remaining continuous filter. This sampler is placed on the output of the controlled member in order to permit the mathematical substitution of an equivalent discrete filter transfer function, $G^*(s)$, for the continuous $G(s)$. If this were not done the output of the system would be continuous and would have to be represented by an infinite number of terms, as previously mentioned.

Again applying the criteria for equivalence established by equations 6 and 7, the system shown in Fig. 2(D) is reduced to that of Fig. 2(E) from which the over-all discrete system transfer function can be defined as

$$\frac{C^*(s)}{R^*(s)}=\frac{D(z)G^*(s)}{1+D(z)G^*(s)} \tag{8}$$

By algebraic manipulation, equation 8 can be reduced to the form of equation 5, which for convenience is written as

$$\frac{C^*(s)}{R^*(s)}=\frac{\sum_{j=0}^{a}A_jz^j}{1+\sum_{j=1}^{b}B_jz^j} \tag{9}$$

Equation 9 is recognized as the transform of equation 3. The solution of equation 9 can be written immediately as

$$c^*(nT)=\sum_{j=0}^{a}A_jr^*[(n-j)T]-\sum_{j=1}^{b}B_jc^*[(n-j)T] \tag{10}$$

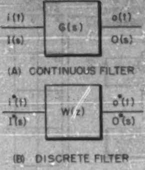

Fig. 1. Continuous and discrete-filters

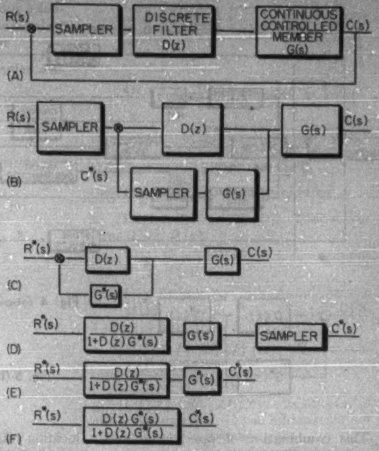

Fig. 2. System reduction

and the exact response can be evaluated at each sampling instant by $(a+b+1)$ multiplications and an equal number of additions.

A sampled response evaluated by this procedure must be computed at every sampling instant for monotonically increasing values of time. When it is necessary to evaluate the response at a given $t=nT$, the indicated operations must be performed $n+1$ times. If a and b are large, this presents a formidable manual-computing problem.

The problems of defining continuous filters as equivalent discrete filters, system reduction, and response evaluation are solved by elementary algebraic and logical processes which can readily be performed on a general-purpose digital computer.

System Reduction and Response Evaluation Performed on IBM Type 650

COMPUTER PROGRAMS

To minimize the time between definition and solution of sampled data systems a number of operational and logical programs are compiled to form a "library" routine, which is one designed for the solution of problems of a recurrent nature.

An operational program is one which will transform one set of data into another by arithmetic processes, as an example, one which will determine the real and complex roots of a polynomial of any order up to some specified limit. The only variations encountered in this problem are the polynomial coefficients. To obtain the roots of a given polynomial it is necessary only to enter the coefficients into predetermined storage locations and instruct the computer to begin the operations necessary to compute the corresponding roots. As the roots are obtained they are placed in sequential order in other preassigned storage locations.

The users of this program need have no detailed knowledge of the computer operations used to obtain the results. It is necessary only to know how to locate input data and where to find the output data. Results of a given input must either be displayed or moved to other storage locations before a new set of coefficients is processed.

When a group of operational routines is collected or designed for the solution of a given type of problem it is profitable to develop logical programs to procure and position input data, relocate results, and select the sequence of operations. The logical program, in turn, can be controlled by coded instructions.

Fig. 4 (above). Interpretive computer program

Fig. 5 (left). Sampled data system

This combination of operational and logical programs controlled by coded instruction is called an interpretive system and is designed to reduce the number of coded instructions required to solve a particular problem. One coded instruction may be used to control the selection and manipulation of large numbers of data.

When the logical program receives a coded instruction, it receives a series of numbers which it separates into groups, thus:

[*OP*] [*A*] [*B*] [*C*]

These numbers are decoded or interpreted for information which designates the operation to be performed, [*OP*], the general storage location of input data, [*A*] and [*B*], and the general storage location into which output data is to be placed, [*C*].

Once the operational and logical programs are compiled into a library routine, the only programming necessary is the coding of instructions applicable to a specific problem. The simplicity of writing these coded instructions will be illustrated in a later section in conjunction with Fig. 4 which outlines an interpretive system.

Equivalent Discrete Filters

The part of the library program used to reduce a continuous filter and sampler combination to an equivalent discrete filter is composed of programs designed to perform the following processes:

1. Determine the real and complex roots of a polynomial.
2. Determine the coefficients for the partial fractions[3] of equation 6.
3. Determine the coefficients of *z* in equation 7.
4. Add polynomial ratios over a least common denominator to alter the form of equation 7 to that of equation 5.

For a continuous transfer function having a fifth-order denominator this entire procedure requires only about 40 seconds of computing time on the IBM *650*.

Roof-finding procedures can be found in books[3] on numerical methods and the determination of partial fractions by computer methods can be found in reference 2. Determining the coefficients of *z* of equation 7 is a simple and straightforward process of function evaluation.

The addition of polynomial ratios

$$\frac{P_{11}(z)}{P_{21}(z)}+\frac{P_{12}(z)}{P_{22}(z)}=\frac{P_{13}(z)}{P_{23}(z)} \tag{11}$$

by interpretive methods is accomplished by an operational program designed to perform

$$\frac{P_{11}(z)P_{22}(z)+P_{21}(z)P_{12}(z)}{P_{21}(z)P_{22}(z)}=\frac{P_{13}(z)}{P_{23}(z)} \tag{12}$$

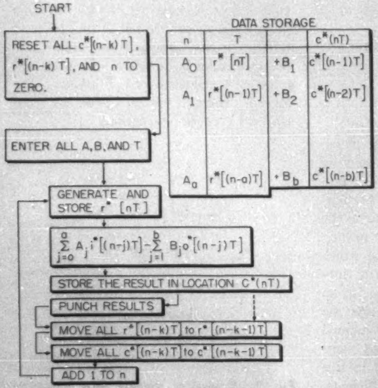
and a logical program which will obtain four sets of input data and store two sets of results if each polynomial is considered separately.

To keep the programming as simple and compact as possible, all polynomials are assumed to have *n* terms; zero coefficients are introduced to fulfill this assumption. The coefficients of the denominator are stored in order immediately after the coefficients of the numerator, and the interpretive program is designed to move groups of 2*n* units of data whenever an operation involves ratios of polynomials. The location of the first coefficient of a polynomial ratio is given in the coded instruction.

The operation code for the addition of polynomial ratios will be designated as [ADD *P*].

System Reduction

After all transfer functions are defined in the form of equation 5, the over-all system transfer function is obtained by two basic operations:



START
RESET ALL c*[(n-k)T], r*[(n-k)T], AND n TO ZERO.
ENTER ALL A, B, AND T
GENERATE AND STORE r* [nT]
$\sum_{j=0}^{a} A_j i^*[(n-j)T]-\sum_{j=1}^{b} B_j o^*[(n-j)T]$
STORE THE RESULT IN LOCATION c*(nT)

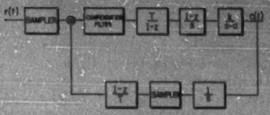
Fig. 9 (right). Sampled data system



1. Adding polynomial ratios over a least common denominator.

2. Multiplying polynomial ratios.

For the system of Fig. 5 with $n = 10$, less than 10 seconds are required by the IBM *650* to determine the over-all system transfer function.

The multiplication of polynomial ratios [MULT *P*] is done by an operational routine designed to perform the operation

$$\frac{P_{11}(z)}{P_{21}(z)}\,\frac{P_{12}(z)}{P_{22}(z)}=\frac{P_{13}(z)}{P_{23}(z)} \tag{13}$$

The reduction of a feedback loop requires the following operation on a combination of polynomials

$$\frac{\dfrac{P_{11}(z)}{P_{21}(z)}}{1+\dfrac{P_{12}(z)}{P_{22}(z)}\,\dfrac{P_{13}(z)}{P_{23}(z)}}=\frac{P_{14}(z)}{P_{24}(z)} \tag{14}$$

By applying the program for the multiplication of polynomial ratios and then the program for addition, the denominator of the left-hand side is reduced to one ratio of polynomials. To complete the problem, a division of polynomial ratios must be performed. An operation code [DIV *P*] and its associated logic is designed to invert the denominator, then the same logical and operational routines which effect the multiplication of polynomial ratios may be used.

When positive feedback loops are encountered, it is necessary to subtract polynomial ratios. For this purpose an operation code [SUB *P*] and associated logic is designed to reverse the signs of the proper coefficients so that the logical and operational routines for addition of polynomial ratios may be used.

RESPONSE EVALUATION

If the transform of the sampled input can be specified in closed form, the system can be reduced by including the input transform with the system transfer function, thus defining an equivalent system whose input is a unit impulse at $t = 0+$. This simplifies the input function generation.

The response function, equation 10, is evaluated by the program shown in Fig. 6. When the system input is a unit impulse at $t = 0+$, the function generator enters a (+1) into the storage location assigned for $r^*(nT)$ at $t = 0$, and thereafter enters zero into this location. In general, the function generator must functionally or logically define $r^*(nT)$ for all values of n.

Since the function generator is part of the problem input data, this evaluation program will be complete, when the coefficients of the difference equation are properly placed. An operation code [EVAL] and its associated logic is established to move the coefficients of the transfer function into the evaluation program and begin evaluating the response at sampling instants.

The evaluation program is shown as a closed loop and, once entered, it continues to evaluate the function for successive values of time. When this loop characteristic is undesirable, simple program alterations are made to satisfy particular problem requirements.

To illustrate the simplicity of using interpretive computer programs, the system of Fig. 5 will be reduced and evaluated with five instructions whose operation codes involve polynomial ratio manipulation.

Assuming an interpretative routine as shown in Fig. 4, if

$D(z)$ is stored in general storage A,
$G^*(s)$ is stored in general storage B, and
(1/1) is stored in general storage C,

then the coded instructions would be

1. [MULT *P*] [*A*] [*B*] [*D*]. *D* now contains $G^*(s)\,D(z)$

2. [ADD *P*] [*C*] [*D*] [*E*]. *E* now contains $1+G^*(s)\,D(z)$

3. [DIV *P*] [*A*] [*E*] [*F*]. *F* now contains $\dfrac{D(z)}{1+G^*(s)\,D(z)}$

4. [MULT *P*] [*B*] [*F*] [*H*]. *H* now contains $\dfrac{D(z)\,G^*(s)}{1+G^*(s)\,D(z)}$

5. [EVAL] [*H*] [*X*] [*X*]. Evaluation of difference equation. [*X*] is information not applicable to this operation code.

NONLINEAR SYSTEMS

Theoretically, there is only one restriction placed on a sampled input; it must be finite in magnitude. There need be no correlation whatever between samples at $t = nT$ and $t = (n \pm 1)\,T$. Therefore sampled inputs to a linear discrete filter may be outputs of a nonlinear function generator.

By using the program in Fig. 6 as a unit building block to represent linear portions of a system, it is possible to simulate systems which contain nonlinear discrete elements with a minimum of effort, since all of the linear portions may be reduced and evaluated by the methods outlined. For example, to represent the system of Fig. 7, the only additional programming necessary would be to simulate the nonlinear discrete filter and to open the loop in the evaluation program.

CONTINUOUS SYSTEMS

Although the discussion to this point has been directed towards the solution of sampled data systems, the programs considered may be applied to continuous linear systems.

The programs concerned with operations on polynomial ratios are applicable for the reduction of continuous systems to a single ratio of polynomials which can be manipulated to reveal response data.

When applying classical methods to evaluate the response of a system defined by

$$C(s)=R(s)G(s)=\sum_{j=1}^{n}\frac{k_j}{s-a_j} \tag{15}$$

it is usually necessary to compute exponential and trigonometric functions for each time point.

By defining an equivalent $C^*(s)$ for $C(s)$, as shown in Fig. 8, trigonometric and exponential functions need be evaluated only once for a given system, system input, and desired sampling period to obtain the coefficients of z in equation 7. Then the solution of the system can be reduced to repetitive evaluation of equation 10. Evaluating the response of continuous systems by this method reduced computing time by a factor of about 10.

Since the difference equation representing the continuous time function is mathematically exact at sampling instants, the accuracy of the computed solution is affected only by performing arithmetic operations on numbers which have been rounded to 8 or 10 digits. The truncation error introduced by applying conventional numerical techniques to the solution of linear differential equations is eliminated.

Conclusion

The library programs discussed can be designed for the IBM *650* to obtain fast and accurate solutions of sampled data systems arising in the design of discrete control elements. One example of the systems studied is shown in Fig. 9. For a particular set of parameters used, the output function of this system was evaluated at the rate of 100 points per minute, and less than one minute was required to obtain complete response data.

The computer processes discussed are simple logical and algebraic operations when considered independently. Their simplicity permits quick and easy programming for general-purpose digital computer application. Properly sequenced on a high-speed computer, these processes combine to form a powerful tool for the evaluation of both sampled and continuous systems.

Subharmonic Response of the Ferroresonant Circuit with Coil Hysteresis

EGON BRENNER
ASSOCIATE MEMBER AIEE

A SERIES circuit consisting of a capacitance, resistance, and a saturable reactor may, because of the nonlinearity, have a markedly different response from that of the corresponding linear circuit when a periodic voltage is impressed.[1-4] This difference manifests itself in two ways: 1. Jump phenomena occur. 2. The response may contain harmonics which are not present in the impressed voltage. The harmonics may be integral multiples or exact submultiples of the frequency of the impressed voltage. This paper deals with subharmonic response, that is the fundamental frequency of the response is an exact submultiple of the impressed frequency. Specifically, the introduction of an idealized nonlinear inductor makes possible the calculation of the effect of hysteresis in the iron on the response; it also makes possible such calculation of the effect of the impressed wave form. Various types and orders of subharmonic response are predicted and their dependence on two normalized parameters is established theoretically and experimentally.

The basic equation for the series RLC (resistance-inductance-capacitance) circuit is

$$d\psi/dt+Ri+\frac{1}{C}\int i\,dt=v(t) \tag{1}$$

where ψ represents the flux linkages. In addition $i=i(\psi)$ where the functional relationship is not linear. For sufficiently small series resistance and for sinusoidal impressed voltage equation 1 may be reduced to the Duffing equation which follows

$$y''+\alpha y'+f(y)=P\sin\omega t \tag{2}$$

where y represents normalized flux linkages, P normalized voltage amplitude and α is a dissipation parameter.[5,6] The function $f(y)$ represents a (normalized) flux-linkage current relationship. A method which has been successfully used to investigate subharmonic response consists of formulating $f(y)$ as a polynomial by applying curve fitting to the normal induction curve of the iron. Equation 2 is then treated by various approximation methods of the theory of ordinary nonlinear differential equations, e.g., perturbation, Fourier coefficient comparison, and the method of varying amplitude and phase.[7-9]

This approach, however, is not fruitful in the problem at hand because: 1. Hysteresis in the iron cannot be included. 2. Nonsinusoidal periodic wave forms are to be considered as well as sinusoids. 3. Small nonlinearity as required by the formulation of equation 2 is often unrealistic.

A physically meaningful approach was taken by Travis and Weygant, who idealized the normal induction curve somewhat and carried through a piecewise linear analysis with sinusoids applied.[10] Their approximation for the induction curve, shown in Fig. 1, assigns infinite slope to the flux-linkage current curve in the unsaturated region. As a result the capacitor charge can change only during an excursion into saturation; at other times it is "trapped" on the capacitor. This concept of trapped charge is a plausible physical explanation of subharmonic response.

It has been used and extended in the following.

Paper 56-686, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted January 4, 1956; made available for printing May 24, 1956.

EGON BRENNER is with The City College of New York, New York, N. Y.

This paper is abstracted from a dissertation submitted in partial fulfillment of the requirements for the degree of Doctor of Electrical Engineering at the Polytechnic Institute of Brooklyn in June 1955. The author is grateful to Dr. Ernst Weber of the Polytechnic Institute of Brooklyn for his expert guidance and many fruitful suggestions. Special thanks are also due Dr. E. J. Smith for his generous help and encouragement. The assistance of Mr. Ken Lian in furnishing the coils used in the experiments is gratefully acknowledged. The research was supported in part by the U. S. Navy under contract no. *Nonr 835(15)*.

Ideal Nonlinear Inductor

The idealizations which are introduced in the analytical portions of this paper consist essentially of assigning infinite slope to the flux-linkage current curve in the unsaturated region, and zero slope in the saturated region. In addition, hysteresis is included but the series (ohmic) resistance of the coil is neglected.

IDEAL HYSTERESISLESS INDUCTOR

The nonlinearity of an inductor without hysteresis is idealized completely by defining: $i=0$ for $-\psi_s<\psi<\psi_s$ and $d\psi/di=0$ for $|\psi|=\psi_s$. This is illustrated in Fig. 2(A).

IDEAL INDUCTOR WITH HYSTERESIS

For the hysteresis loop corresponding to saturation flux density, Fig. 2(B), define: $i=\pm i_c$ for $|\psi|<\psi_s$ and $d\psi/di=0$ for $|\psi|=\psi_s$. For smaller loops assume that $i_c/i_1=\psi_s/\psi_1$. For minor loops, as illustrated in Fig. 2(C), assume that if ψ has been decreasing from ψ_1 to ψ_2 and if at $\psi=\psi_2$, $d\psi/dt$ becomes positive, then ψ will increase with $i=i_2$ where $\psi_1/i_1=\psi_2/i_2$. This heuristic assumption concerning minor loops will be referred to as the "proportional rule." It is also noted that the hysteresisless inductor as defined in the foregoing is a special case of the inductor with hysteresis for $i_c=0$.

Conditions for Various Responses

The equation governing the idealized circuit is

$$d\psi/dt=v(t)-v_c(t) \tag{3}$$

where $v_c(t)$ represents the capacitor voltage and $v(t)$ is the periodic impressed voltage with half-wave symmetry. Consider, now, an instant of time $t=t_1$ when $d\psi/dt$ is positive so that $v(t_1)>v_c(t_1)$ and the coil is about to enter saturation so that $\psi(t_1)=+\psi_s$. When the coil enters saturation $d\psi/dt$ becomes zero because no further increase in flux linkages is possible. Consequently an impulse of current, $i(t)=C[v(t_1)-v_c(t_1)]\delta(t-t_1)$, will develop to charge the capacitor to the value of impressed voltage. The capacitor voltage will then remain equal to the impressed voltage as long as the impressed voltage increases or remains constant. If the impressed voltage starts to decrease, current in the reverse direction (to discharge the capacitor) will have to flow. Hence, $d\psi/dt$ becomes negative and the counter electromotive force again has a value. One therefore deduces that at the instant of time just before the coil leaves the saturated condition, the capacitor voltage is exactly equal to the impressed voltage.

Since the steady state is to be obtained, these considerations reveal an approach which makes it possible to calculate a typical response cycle in the steady state by starting always with the flux-linkage capacitor-voltage condition as has been stated. It is reasonable to expect the coil to enter the saturated region during the transient for several reasons: 1. The idealization of square loops is expected to be best for the sensitive magnetic materials, which have a high ratio of residual to saturation flux density. 2. Subharmonic response can occur without hysteresis so that the nonlinear effect of saturation must be used for the production of subharmonics. 3. Experimental observation shows that the assumed situation is reasonable.

The method of calculation of response, then consists of starting at the beginning of a half-cycle when $v(t)$ starts to decrease, and solving a sequence of linear equations until the coil again enters saturation. The largest interval for a piece of the solution which can be used in this method is a half-cycle of impressed voltage. The responses which are obtained fall into the following categories under the condition cited, assuming that the calculation is started at $\psi=+\psi_s$ (positive saturation):

1. If $\psi=-\psi_s$ (negative saturation) is reached during or at the end of the first half-cycle, periodicity is established with the fundamental frequency of the response equal to the impressed frequency. Since the second half-cycle will be the exact negative of the first half-cycle ("mirror" symmetry) this response will be termed "symmetrical fundamental" response.

2. If positive saturation is reached at the end of the second half-cycle or before, and negative saturation has not been reached previously then the response is again of fundamental frequency but it will not have mirror symmetry. This response will be termed as "unsymmetrical fundamental."

3. If neither condition 1 nor condition 2 is fulfilled, then more than one cycle of impressed voltage is necessary to establish periodicity and the response is "subharmonic." Subharmonic response may be symmetrical or unsymmetrical depending on whether periodicity is established by entering negative or positive saturation respectively. The subharmonic frequency may be an even $1/(2n)$ or an odd $1/(2n-1)$ submultiple of the impressed frequency.

Method of Calculation

In this section the method of calculation is outlined. Examples of typical calculations are given in Appendix I.

UNSATURATED REGION

Because a calculation is carried through from the time the coil leaves saturation until it enters saturation again, the method of calculating responses consists of solving the appropriate circuit equations with the coil unsaturated. Moreover, except for the transitions from an ascending to a descending portion of a hysteresis loop when $d\psi/dt$ changes sign, the current is constant. A typical equa-

Table I. Normalization and Notation

Physical Quantity	Normalized Quantity

C—Trapezoidal wave

tion for calculating a section of the response for constant current is

$$d\psi/dt=v(t)-\left(v_{co}-\frac{it}{C}\right) \tag{4}$$

which integrates to

$$\psi-\psi_0=\int_{t_0}^{t}v(\tau)d\tau-v_{co}{}^{(t-t_0)}+\frac{1}{2C}i(t-t_0)^2 \tag{5}$$

where ψ_0 and v_{co} are the initial values for the section of the response which is being calculated. They must be identical to the final values of the preceding calculation.

Because of the minor hysteresis loops it is clear that an equation typified by equation 4 is valid only as long as $d\psi/dt$ does not change sign. The solution, equation 5, is then used only in that interval of time. At the instant when $d\psi/dt$ becomes zero, equation 5 gives the initial value of ψ for the next calculation. The value of i to be used in the next calculation is determined by the proportional rule. The transition to the new value of current takes place in zero time with no change in capacitor charge because an impulse of current cannot develop in the idealized inductor when the coil is not in saturation.

NORMALIZATION

To reduce the problem to the minimum number of variables and parameters, the normalizations shown in Table I are introduced. In this table E is the amplitude of the impressed voltage which has period T. These normalized quantities are not only convenient but have physical significance:

1. $ET/2$, which is used to normalize ψ, is equal to the flux linkages which would be produced if a constant voltage E were applied to the coil directly for a half-cycle.
2. The parameter a is the ratio of the charge on the capacitor due to a current i for a half-cycle to the charge on the capacitor if a constant amplitude E is applied.
3. The parameter K measures the ratio of width to height of the largest hysteresis loop. Note that it is independent of the impressed amplitude E.

Responses of Ideal Circuit

SQUARE-WAVE RESPONSE

The use of square waves for obtaining typical response in linear circuits is extensive because of the validity of superposition. While in nonlinear systems the response to no particular wave form can be considered typical in general, analysis and experimentation using symmetrical square-wave excitation is fruitful in the problem under consideration. The problem of phasing (instantaneous value) in particular is minimized because of the flatness of the square wave. Moreover, the square wave has not only the virtue of leading to simple calculations which yield significant results; it can also be easily produced.

If the symmetrical square waves shown in Fig. 3(A) are applied, the calculation may be started at $t=0$ with $v(t)=-E$, $y=y_s(\psi=\psi_s)$, $u=+1(v_c=+E)$, $a=a_c(i=i_c)$ and carried through sectionally as already outlined. Some details of these calculations are given in Appendix I. The significant conclusion is that a series of inequalities involving only y_s and a_c

or K determine the type of response obtained. These inequalities divide the y_s-a_c plane or the y_s-K plane into regions, each region corresponding to a particular type of response. Fig. 4 shows the y_s-a_c plane and Fig. 5 shows the y_s-K plane. In these illustrations the response regions are identified as far as they were calculated. (In the exceedingly narrow regions of subharmonic response in the y_s-K plane, above $K \approx 1/2$, the regions are shown somewhat simplified. Where the boundaries of these regions are so close together, the indicated order of subharmonic may not occur.)

Conclusions from Figs. 4 and 5

The following conclusions may be drawn from the analysis of the idealized circuits with square-wave excitation, regarding the influence of hysteresis on subharmonic response:

1. Comparison of the analyses with and without hysteresis ($a_c=0$) reveals that with a finite-width hysteresis loop two types of harmonic and subharmonic response are possible, i.e., symmetrical and unsymmetrical, while only the symmetrical responses are possible without hysteresis.

2. The circuit response to square waves is determined by two parameters: y_s, the saturation flux linkages normalized with respect to the half-cycle (applied) voltage-integral; and K, the normalized hysteresis loop width.

3. If the normalized hysteresis loop width exceeds a critical value ($K>2$) no subharmonics can occur. This shows that the energy dissipating feature of hysteresis has the same effect on suppressing subharmonic responses as does ohmic damping.

4. Unsymmetrical responses are due to hysteresis. The even-order subharmonics can also occur only with nonzero width hysteresis loop (for this type of excitation). Moreover, the response regions shown in the y_s-K plane show that the regions of unsymmetrical subharmonic response adjoin the region of unsymmetrical fundamental response. Thus when, for example, the loop width is below the critical value referred to in item 3, if y_s is increased from a very low value (or the amplitude of the applied voltage is decreased from a correspondingly large value), one will observe the following responses in sequence: fundamental, one-third harmonic, one-fifth harmonic, and all other higher odd subharmonics; then the even-order subharmonics in the inverse order, i.e., the one-quarter, the one-half, and finally unsymmetrical fundamental response. The odd-order subharmonics are symmetrical, the even-order unsymmetrical.

5. Within a region on the response plane (y_s-K plane), the subharmonics are stable (because of the idealization of the coil), so that a change of parameter within a region will change the wave form of the response but not its fundamental frequency.

6. As is implicit throughout the analysis (in view of the proportional rule), the minor hysteresis loops are the property of hysteresis, which is responsible for the possibility of even-order unsymmetrical subharmonic response.

Triangular Wave Form

The results obtained with the triangular wave form of Fig. 3(B) impressed are summarized in the response diagram (y_s-a_c graph) of Fig. 6. The calculations in this case were carried only to the point where the similarities and differences between Fig. 6 and Fig. 4 became evident. Note that for this wave form even-order subharmonics may occur with zero-width hysteresis loop. Unsymmetrical response can, however, occur only for finite-width hysteresis loop ($a_c>0$).

Trapezoidal Wave Form

The boundary curves between symmetrical fundamental and other responses for the trapezoidal wave form of Fig. 3(C) impressed, are shown in Fig. 7 for several trapezoids. It is noted that the triangular and square-wave cases are the limiting cases of trapezoids for zero and maximum "flat top" respectively. For this reason it is concluded that the dependence of subharmonic regions in the response diagram on two parameters (y_s and K) is, within the limitations of the idealizations, generally true for periodic wave forms. Thus, for example, the response to sinusoids may be approximated by obtaining the response to a trapezoid. This procedure avoids the difficulty of solving transcendental equations which sinusoids introduce into a piecewise linear analysis.

Theoretical Discussion of Idealizations

The analysis based on the idealizations reveals regions of subharmonic response which depend on the normalized parameters. Although this result can qualitatively be verified in the laboratory, it is appropriate here to discuss each feature of the idealizations from a theoretical viewpoint so that the extent of the validity of the analysis may be judged.

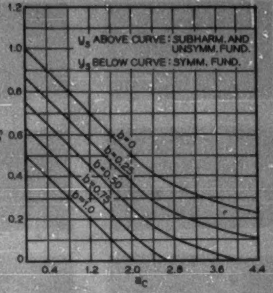

Fig. 7. Boundary between symmetrical fundamental and other responses for trapezoidal wave forms impressed

Series Resistance

Omitting series resistance from the analysis does not influence the validity of the results provided that the resistance is sufficiently small, as smallness is defined in this section.

In the saturated region, the inclusion of series resistance in the analysis shows that the impulse of current which was previously obtained when the coil enters saturation is actually an exponential decay. If the period T of the impressed wave form is large compared to the time constant RC, then the capacitor charge just before the coil emerges from saturation will still equal the (instantaneous) value of the impressed voltage. The same inequality ($T>>RC$) will ensure that the volt drop across the series resistance in the unsaturated condition does not materially affect either $d\psi/dt$ or the capacitor voltage.

Slope in Unsaturated Region

If the assumption of infinite slope of the $\psi-i$ curve in the unsaturated region is relaxed to permit the line to have large but finite slope of value L_0, then the circuit in this section is a linear RLC circuit. Linear analysis shows that if the circuit is taken as very underdamped ($4L_0>>R^2C$) then the change in capacitor charge per half-cycle differs only slightly from the value obtained with the infinite slope assumption, provided also that the impressed frequency is much larger than the natural frequency of the RLC circuit.

Abrupt Breaks and Slope in Saturated Region

The lack of abrupt breaks in a realistic coil characteristics may be expected to invalidate the quantitative results which are calculated (on the idealized basis) for the higher-order subharmonics, because for these responses the coil would be near the region of the rapidly changing slope for a considerable fraction of an impressed voltage cycle.

The assumption of zero slope in the saturated region is mostly responsible for the approximate nature of the numerical results. Permitting the coil characteristics to have finite but small slope (of value L) again results in a linear *RLC* circuit problem. Now, however, both R and L are small so that this circuit may be either underdamped or overdamped. Consequently the capacitor charge, at the instant just before the coil emerges from saturation, may be larger or smaller than the instantaneous value of the impressed voltage. Hence the corresponding initial condition used in the calculations may be unrealistic. These considerations do not, however, invalidate the type of response diagram expected; rather they modify the relative sizes of the various regions.

Capacitor Charge; Conclusions

With the idealized characteristics, transitions from descending to ascending (or vice versa) portions of the hysteresis loop take place in zero time with no change in capacitor charge. In an actual coil the minor loops will extend into saturation and the transition does not take place with constant flux density. In view of these and the other considerations, the responses of an actual circuit may depart from ideal in these respects:

1. There would be quantitative differences with respect to the width of the response regions.
2. Additional regions (i.e., types or orders of subharmonics) may occur in the realistic case; in particular, unsymmetrical odd orders may be observed.
3. No changes in the general type of response diagram are expected

Experimental Results

The experimental work was carried out to determine the extent to which the type of response depends on the normalized parameters. Since no exact numerical agreement is expected, the parameters Y and W as defined in Table I are used to replace y_s and K respectively.

Square-Wave Tests

Square waves of reasonable rise time and flatness, Fig. 8(A), were applied to an RLC series circuit (in which the coil was wound on a *4-79* Mo Permalloy core) and the voltage was increased from zero ($Y=$ infinite). Initially unsymmetrical fundamental response, Fig. 8(B), was obtained; then the one-half harmonic, Fig. 8(C), occurred. The lowest amplitude of impressed voltage for which the one-half harmonic was stable was recorded for five frequencies and various capacitance values. The results are shown in Fig. 9. The curve formed by the points of Fig. 9 corresponds to the boundary between regions 2 and 4 in Fig. 5 (or Fig. 4).

In Fig. 10 the points of Fig. 9 for the three lowest frequencies are shown as line *1*. Line *2* is the (averaged) curve (for these three frequencies) at which the transition to the one-quarter harmonic occurred. This type of response is shown in Fig. 8(D). Line *3*, Fig. 10, is within the region of an unsymmetrical one-third harmonic, shown in Fig. 8(E), which is not predicted by the ideal analysis. This response, as well as other responses between lines 3 and 4 are discussed in Appendix II. Near line *4* the unsymmetrical fundamental, Fig. 8(F) occurs briefly, then symmetrical responses, Fig. 8(G) and (H), fundamental harmonic and one-third harmonic respectively occur. Further discussion is given in Appendix II.

Sinusoidal Tests

Sinusoidal voltage impressed on the same circuit yielded similar results. The dependence of the response regions on the normalized parameters is most clearly established by the curve shown in Fig. 11. This curve is the transition from unsymmetrical fundamental response, Fig. 12 (B), to the one-half harmonic, see Fig. 12(C). As the voltage amplitude is further increased, the higher-order subharmonics occur in narrow regions and these regions are therefore not clearly defined. For still smaller values of Y the symmetrical one-third harmonic, Fig. 12(D) and (E), and then symmetrical fundamental ferroresonant response Fig. 12(F) occurs.

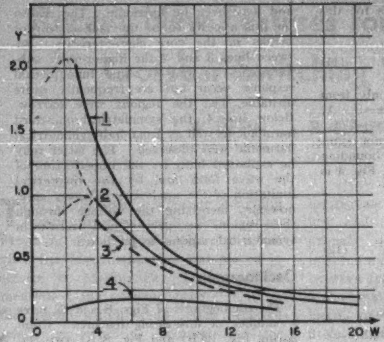

Fig. 10 (left). Square-wave test results: response regions

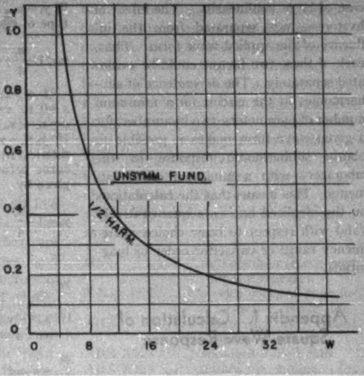

Fig. 11 (right). Sinusoidal test results: boundary for transition to one-half harmonic

CONSISTENCY OF RESULTS

The sequence of occurrence of the various responses were consistent and they were duplicated with a second coil using a Hypernick *V* core. The oscillograms for the latter case were similar, and are omitted in this presentation. It is particularly noted that a response condition, once obtained by varying one parameter in the circuit (e.g., capacitance), could be duplicated by varying another parameter (e.g., frequency) so that the same condition for the normalized parameters was obtained provided, of course, that the response condition was not too near the boundary of a region.

Conclusions

The analysis and the experimental results lead to several conclusions which may be classified in four categories, as follows.

PRODUCTION OF SUBHARMONICS

Subharmonics occur because of the nonlinearity of the coil. When the coil enters saturation, a change in capacitor charge occurs. The release of this capacitor charge in the case of a hysteresisless coil is delayed until the coil again enters saturation. This is the trapped-charge concept of Travis and Weygant.[10] In the case of the coil with hysteresis, the release of the trapped charge is controlled by the unsaturated inductance or the coercive force. A trapped or partially trapped charge may therefore be considered a basic explanation of subharmonics.

The type and order of subharmonic which may occur is determined by three factors: the wave form of the applied voltage, the amplitude and frequency of the applied voltage and hence by the normalized saturation flux linkages, and the normalized hysteresis loop width.

The type and order of subharmonics for a given circuit may be summarized (for a given applied voltage wave form) in a response diagram which is a plot of regions in the y_s (or Y) (normalized saturation flux linkage)$-K$ (or W) (normalized loop width) plane. If the idealizations of this analysis are used, the response diagram shows the conditions for which a given type and order of subharmonic may occur. With actual coils the size and number of the response regions are modified. The series resistance of the circuit must be small or subharmonics cannot occur.

INFLUENCE OF COIL HYSTERESIS

Without hysteresis only symmetrical responses occur. Hysteresis accounts for unsymmetrical responses of both fundamental and subharmonic variety. If the hysteresis loop width exceeds a critical value, no subharmonics can occur.

INFLUENCE OF IMPRESSED WAVE FORMS

Symmetrical even- and odd-order subharmonics are predicted with periodic wave forms having quarter-wave symmetry, half-wave monotonicity and zero average value except for the symmetrical square wave. For the latter case, only symmetrical odd orders are predicted.

A slight change in wave form (such as changing from one trapezoidal type to another of the same frequency but slightly longer flat top) produces only correspondingly small changes in the response diagram. The actual current wave forms within a response type, however, are sensitive functions of the voltage wave forms.

VALUE OF ANALYSIS WITH IDEALIZED CHARACTERISTICS

The work presented in the foregoing shows that the sectional linearization, so as to emphasize the nonlinearity and consequent idealization of coil characteristics, is of value in furthering a basic understanding of subharmonic response from the circuit point of view in the realistic

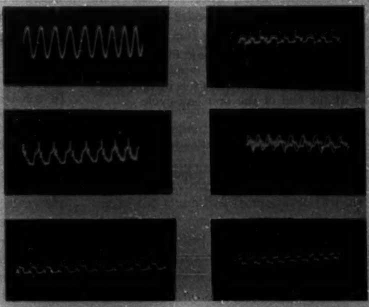

Fig. 12. Current oscillograms obtained by increasing sine wave amplitude in the test circuit at 900 cycles per second. Capacitance 0.04 microfarad

a—Impressed wave form
b—Unsymmetrical fundamental response
c—One-half harmonic
d—One-third harmonic
e—Same as (d) with impressed wave form superposed
f—Symmetrical fundamental response

case of large nonlinearity. The effect of hysteresis was separated from the influence of the applied wave form. Thus, each of these two factors could be evaluated separately. The dependence of subharmonics in the circuit on a minimum number of parameters, two in number, for a given wave form makes it possible to obtain subharmonic response in the laboratory with a minimum of adjustments. This means that the calculations on the idealized basis are quantitatively valid with respect to basic choice of frequency range or capacitor order of magnitude.

Appendix I. Calculation of Square-Wave Response

Calculation Without Hysteresis

The wave form of Fig. 3(A) is applied to the circuit, series resistance ignored, and the coil characteristics of Fig. 2(A) used. Starting with $y=+y_s$, $u=+1$ and $v(0)=-E$, the normalized circuit equation for the first half-cycle of impressed voltage is

$$dy/dx=-2;\ 0<x<1 \tag{6}$$

Integrating

$$y=y_s-2x \quad 0<x<1 \tag{7}$$

so that symmetrical fundamental response occurs for $y_s \leq 1$. If $y_s>1$ then, during the second half-cycle $dy/dx=0$, so that subharmonic response occurs. During the third half-cycle, let $x'=x-2$

$$y=y_s-2-2x',\ 0<x'<1 \tag{8}$$

Hence, if $1<y_s\leq 2$ "negative" saturation $(y=-y_s)$ is reached during or at the end of the third half-cycle, so that symmetrical one-third harmonic response results. In general if $m-1<y_s<m$, the $1/(2m-1)$ harmonic occurs (with m as an integer).

Calculation With Hysteresis: First Half-Cycle

The initial conditions are the same as without hysteresis. Hence for the first half-cycle

$$\frac{dy}{dx}=1-u;\ u=1-a_cx \text{ or } \frac{dy}{dx}=-2+a_cx \tag{9}$$

If $a_c<2, dy/dx$ is monotonic for the first half-cycle and equation 9 applies up to $x=1$. In this case equation 9 is integrated, and at the end of the first half-cycle

$$y(1)=y_1=y_s-2+\frac{a_c}{2} \tag{10}$$

Symmetrical fundamental response occurs if y_1-y_s, so that the conditions for this type of response are

$$y_s<1-\frac{a_c}{4};\ a_c<2 \tag{11}$$

If $a_c>2$, equation 9 applies only from $x=0$ to $x=x_a=2/a_c$, when $dy/dx=0$. At $x=x_a$ $u(x_a)=-1$ and $y(x_a)=y_a=y_s-2/a_c$. If $y_a\leq -y_s$ the response is again symmetrical-fundamental so that the bounding curve between region 1 and 3 in Fig. 4 is given by

$$\begin{aligned} y_s&=1-\frac{a_c}{4} && a_c<2 \\ y_s&=\frac{1}{a_c} && a_c>2 \end{aligned} \tag{12}$$

If $y_a>-y_s$, define $n_a=y_a/y_s$ and set $x'=x-x_a$. For the remainder of this half-cycle

$$\frac{dy}{dx'}=n_aa_cx' \tag{13}$$

where $-n_aa_c$ is the value of a adjusted in accordance with the proportional rule. If $n_a>0$, y increases. If $n_a<0$ equation 13 indicates decreasing y with positive current, an impossible condition (with the idealized characteristics) so that $y=y_a$ (with $a=0$) until the impressed voltage reverses. In either case the flux linkages will be increasing during the second half-cycle at least as rapidly as during the first half-cycle so that the condition $y_s>1/a_c$ for $a_c>2$ results in unsymmetrical fundamental response.

Subsequent Half-Cycles

One need only consider the case

$$y_s>1-\frac{a_c}{4};\ a_c<2 \tag{14}$$

since the other cases are completed in the preceding paragraph. Now define $n_1=y_1/y_s$ where y_1 is given in equation 10. During the second half-cycle $(x^1=x-1)$

$$\frac{dy}{dx'}=1-(1-a_c[1+n_1x'])\quad 0<x'<1 \tag{15}$$

The procedure now follows the treatment of equation 9, and the next curve desired is the boundary between region 2 and 4 in Fig. 4. In a similar manner the other curves in Figs. 4 and 5 are calculated.

Appendix II. Discussion of Experimental Results

Discussion of Fig. 10

In constructing line 1 of Fig. 10, only the results of the frequencies from $1-2Kc$ were used because of the variation of coercive force with frequency. Near the boundary of each region, instability occurs. The response there is not clearly defined and may even be aperiodic. The reason for this appears to be the lack of abrupt breaks in the core characteristics. Between lines 3 and 4 the higher-order subharmonics as well as some fundamental response occur but are frequently quite unstable, i.e., the regions were narrow. Below line 4, the symmetrical one-third harmonic as well as a one-half symmetrical harmonic were observed. The latter may be explained both by the imperfection of the wave form and by the theoretical limitation of the analysis. In every case, however, increasing the voltage through these regions (i.e., decreasing Y) results in symmetrical response as predicted.

Oscillograms

The oscillograms of Figs. 8 and 12 have a number of interesting features. Comparing Fig. 12(B) and Fig. 8(B), two unsymmetrical fundamental responses, it is noted that while the type of response is the same in the two cases, the actual wave forms differ. The same remark applies to Figs. 12(C) and 8(C). The type of observation motivates the statement concerning the wave forms in the second paragraph of the conclusion "Influence of Impressed Wave Forms."

Examination of the oscillograms shows also that in each case of subharmonic response, excursions into saturation take place and that in the intervening regions the current is almost constant except for much smaller excursions into saturation. These observations tend to enhance the value of the idealizations.

Recent New Features for the No. 5 Crossbar Switching System

J. W. DEHN
NONMEMBER AIEE

R. E. HERSEY
NONMEMBER AIEE

THE NUMBER 5 crossbar switching system was described by Korn and by Ferguson[1] in 1950, just a year and a half after the first installation was placed in service at Media, Pa. These authors mentioned the growing need "...for a dial system which would better meet the telephone switching requirements for areas on the outskirts of metropolitan cities and at the same time care for medium-to-large sized offices in other areas." Since that time, the basic switching plan of this system has proved to be so flexible and adaptable that it is finding an ever-expanding application in many new combinations of switching requirements. After a brief review of the basic switching plan described in more detail in the previous article, this paper will cover some of the new features since added to the system.

No. 5 Crossbar System: Basic Switching Plan

Like its forerunner, the No. 1 crossbar system,[2] the No. 5 is an all-relay, and relaylike, switch system. Fig. 1 indicates the major circuits of the system and the manner in which they are interconnected. The blocks called line link frames and trunk link frames represent the crossbar switch frames each having columns of ten primary and ten secondary switches. The quantities of such frames depend upon the number of lines to be served, their calling rates, and average conversational holding time. A single switching unit, usually called a marker group, having four line link frames and two trunk link frames, is the minimum size usually provided and may serve about 2,000 lines. Other marker group sizes range up to 40 line link frames and 20 trunk link frames and may serve up to 40,000 numbers. Arrangements are being made to increase the frame limits to 60 line link and 30 trunk link frames. The primary and secondary switches are interconnected between switches and between frames by links and junctors in a systematic "fanning out" and "interlaced" pattern so that there are always at least ten paths between any line on the left and each trunk on the right. Customers' lines are wired to the verticals of the columns of switches on the left and the various circuits to which customers can be connected are wired to the horizontals of the column of switches on the right. Included on the right, in addition to all the various types of trunks, are the originating registers in which are recorded all the digits of each call as the customer dials them. Tandem-type and toll-type incoming trunks also have an appearance on the verticals of the line link primary switches on the left, in order that calls may be switched through to outgoing trunks. Incoming calls are served by incoming registers capable of receiving the type of pulsing impressed at the far end. On the other hand, certain outgoing calls require outgoing senders capable of delivering the type of pulsing which the far end is arranged to receive. Incoming registers and outgoing senders are connected to their respective trunks through crossbar switch links. All of the major circuits have connections to markers through multicontact relay circuits called connectors. A marker is used for establishing the connections for each call. Details are covered in the Korn-Ferguson paper.[1]

New Features

Some features added to provide improved handling of local and short-haul traffic will be described here.

PRETRANSLATORS

It will be recalled that after a customer has dialed his call into a register, a marker is utilized to complete the desired connection. As customers are permitted direct dialing for more and more of their calls, more variation in the number of digits dialed may be encountered. It therefore becomes desirable to automatically determine completion of dialing without introducing a delay of several seconds awaiting additional digits which may not be dialed. Accordingly, a circuit called a pretranslator[3] has been made available to the originating registers on a selectable basis. This circuit provides means for determining the total number of digits by inspecting the first three (code) digits dialed. The variety of digits which may be dialed can be represented as follows:

O................	zero operator (recognized in the register).
XII or IIX........	service codes such as information, repair, etc.
ABX.............	unintentionally dialed unused local codes.
ABX XXXX......	standard 7-digit calls.
ABX XXXX P...	a few remaining calls with party letters.
XOX.............	unintentionally dialed unused area codes.
XOX ABX XXXX.	direct distance dialed calls.
XOX ABX XXXX P.	direct distance dialed calls with party letter.

As soon as three digits are dialed, they are passed to the pretranslator which can then determine whether 3, 7, 8, 10, or 11 digits are required. Thus, the register can proceed to call the marker immediately when the proper number of digits has been received. Except when O is dialed, the pretranslator functions on all calls. Its holding time is about 150 milliseconds. Usually two, mounted on a single bay 23 inches wide, will be enough for one central office unit; see Fig. 2.

SEPARATE DIAL TONE AND COMPLETING MARKERS

As described in the previous paper, the control of the switching elements is centered in a few common control circuits called markers, which are rapid in operation. A new feature introduced since the previous paper isolates the functions of the marker which control selection of and connection to the originating registers, and places them in a circuit called a "dial tone" marker which has no other function. It will be recalled that in establishing a connection from a line to an originating register, the marker has but one fixed set of functions to perform: It identifies the calling line, chooses an idle originating register associated with one of the trunk link frames, selects a set of links and junctors between the line and register, and, by operating the associated crossbar switch elements, connects the originating line to the register which together returns dial tone to the customer.

Paper 56-667, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted November 21, 1955; made available for printing May 9, 1956.

J. W. DEHN and R. E. HERSEY are with the Bell Telephone Laboratories, Inc., New York, N. Y.

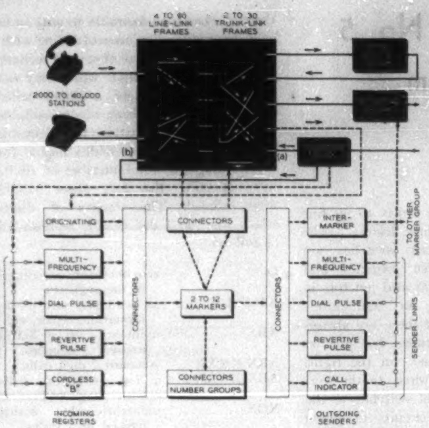

Fig. 1 (left). No. 5 crossbar switching system block diagram. Connection (a) is for terminating connections, and connection (b) is for tandem connections

All other control features remain in another circuit called the completing marker. In this way the unused completing features of the marker are not withheld from use while the dial tone function is activated, and vice versa. This increases marker efficiency, thus reducing over-all marker cost.

Enlarging Over-all Capacity

The limiting parameters of No. 5 crossbar offices have been enlarged as follows:

1. Previously limited to two 10,000-directory-number series and two central office names in each series, arrangements now permit 40,000 directory numbers and six central office names with any desired assignment of each 1,000 numbers to any office name not to exceed 10,000.

2. As a result of this added flexibility, variable calling rates, population distribution, geographic boundaries, etc., many more differences of service and rate treatment become imperative. This is the case especially where a single switching unit serves several areas separated by geographic boundaries. In such cases it is possible that each of the six office names may represent a community sufficiently different from the others to warrant a different rate structure. Accordingly, the number of rate and service classes has been increased from 30 to 60.

3. The customers in some of the areas where No. 5 crossbar will be used have such high calling rates and holding times that the limit of 40 line link frames and 20 trunk link frames will permit only about 6,000 lines to be assigned. This would be wasteful of office names and would require the uneconomical introduction of a second marker group for additional lines. On the other hand, the traffic density is sometimes low enough to allow the number of assigned directory numbers to fall in the areas between 10,000 and 20,000 or between 20,000 and 30,000, or between 30,000 and 40,000. In each case enlarging the array of line link frames and trunk link frames up to 60 and 30 respectively will permit filling out each office code to approximately 10,000 numbers. This increase in number of frames is being provided.

Intermarker Group Operation

When the capacity of one marker group is exceeded, it is frequently desirable to serve additional lines by providing a second marker group in the same building. Switching of calls from one marker group to the other could be handled by the same out-trunking and pulsing methods used when the marker groups are in separate buildings. However, a combination of outgoing and incoming trunk circuits can be provided which is much simpler when both parts are adjacent. Such trunk circuits are called intermarker group trunk circuits. Also, it becomes quite simple to pass information laterally from one marker to another without outpulsing the digital information. This is accomplished by providing "intermarker group sender" circuits associated with intermarker group trunk circuits. Such a sender receives the digital information from a marker of the originating group and passes the same digital information directly into a marker of the other group, as from an incoming register; see Fig. 3. The operation is very rapid and therefore a small group of these senders will handle many calls. A similar group handles calls in the reverse direction. Another type of intermarker group trunk circuit, functioning similarly, operates so that calls originating in one marker group may be switched through the other

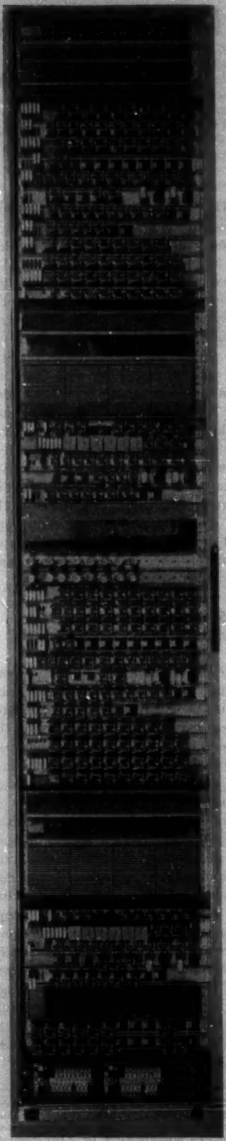

Fig. 2. Two pretranslators on one frame

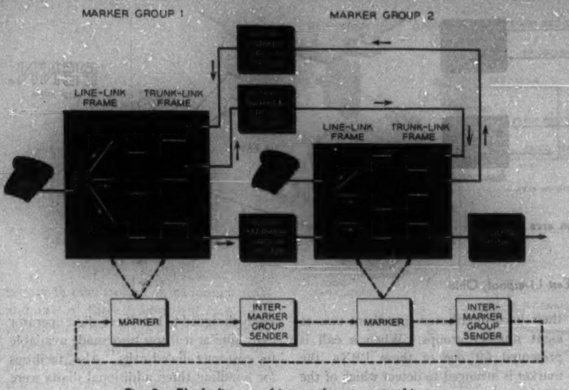

Fig. 3. Block diagram of intermarker group trunking

marker group to any of the outgoing trunks in that marker group. Also provided are the reverse of this, i.e., intermarker group trunk circuits which permit incoming trunks in one marker group to switch calls through to customers in the other marker group.

Junctor Circuit Operation

An interesting arrangement of combined circuitry permits certain types of calls which require special types of supervision and/or control features to be served by a comparatively small group of circuits having the necessary special features. As an example, coin customers require trunk circuits which have various kinds of coin test, coin collect, and coin return features available. For non-coin customers the trunk circuits can be much simpler. Usually the coin traffic is comparatively low and also does not usually coincide with the peaks of non-coin traffic. To route the coin traffic over the non-coin trunks would require that each of a fairly large group of trunks to every destination be provided with both coin and non-coin features. Alternatively two subgroups of trunk circuits, one for coin and the other for non-coin could be provided. To provide the coin features and still realize the economies of a single group of non-coin trunks to each destination, a small special trunk group having the coin features can be provided. This group appears not only as outgoing trunks on the trunk link frames but again as incoming tandem-type trunks on the line link frames; see Fig. 4. Such combined circuits are called junctor circuits. A regular outgoing sender and an incoming register is utilized on each call. The incoming register after receiving the digital information from the sender requests a second marker to route the call through the switches again to one of the non-coin outgoing trunks. Therefore it is neither necessary to provide special features in all outgoing trunk circuits nor to provide duplicate groups of outgoing trunk circuits, having the necessary features, to every destination.

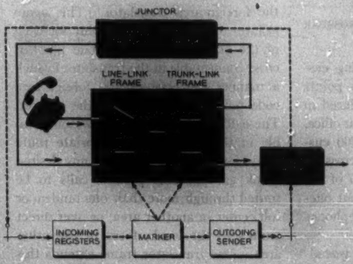

Fig. 4 (left). Block diagram of junctor operation

Marker Pulse Conversion[4]

A feature which utilizes the common control circuits of the system without actually setting up calls through the switches is made use of in connection with operator trunks at a switchboard in the same building; see Fig. 5. In this case the operator selects an outgoing trunk to the desired destination in the switchboard multiple even though the required pulsing to the distant end is not the same as that which the position provides. For example, the position may be provided with multifrequency keying but the distant circuit requires dial pulses. In this case the trunk circuit selected will be split and the cord end will have access to the No. 5 crossbar incoming link and register of the multifrequency type. After the operator keys the digital information into the register, it will call upon a marker to pass the digital information to one of the No. 5 crossbar senders having the appropriate kind of pulsing, and attach the sender to the split trunk for outpulsing. The incoming register and marker are dismissed and, after outpulsing, the sender is released and the talking connection is established through the trunk circuit. No switching path through the line link and trunk link frames is used on this type of connection.

Improved PBX Features

Number group frames are provided, one for each thousand numbers, to indicate to the marker the exact location of each called line and the type of ringing current to apply on party lines. For the usual PBX (private branch exchange) the directory number and all associated lines will appear in one number group.

Where there are large and/or important PBXs it becomes desirable to provide for distribution of the lines over more than one number group. This divides the traffic load to large PBXs so that a given number group will not be called upon for more than its share of the total office load. Some PBXs, such as those handling ticket reservations, provide only as many lines as there are agents. Thus, in some cases when all lines are busy, hundreds of calls may still be offered. For this reason it is

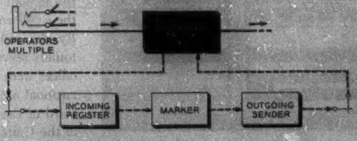

Fig. 5. Block diagram of marker pulse conversion

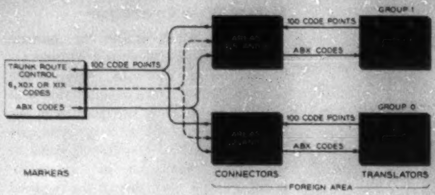

Fig. 6 (above). Block diagram of foreign area translator

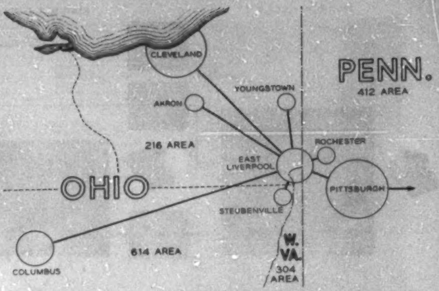

Fig. 8 (right). Foreign area translator used in East Liverpool, Ohio

desirable to be able to recognize such PBX groups as busy without actually entering the number group. New features of this type have been designed into a circuit called a PBX allotter; one is assigned to operate with each marker. With this circuit, ten different PBXs may have their lines distributed into from two to eight number groups. When a call is presented for one of these PBXs, the marker is arranged to detect which of the number groups contain idle lines and then it places the call in one of the number groups which that marker prefers. Different markers have different preferences but each can reach any line. In this way the markers may complete calls to the same PBX without delaying one another.

Features Added for Direct Distance Dialing, Tandem and Toll Use

To a degree greater than was earlier anticipated, No. 5 crossbar offices have been located at points where tandem and toll switching is required. Certain uses include directing codes to allow calls to be routed into and out of other switching areas. Accordingly, for tandem and toll use, outgoing senders, incoming registers, and markers were originally arranged to handle a total of ten digits (plus an eleventh where the fast-disappearing party letters were involved). While early use of 10-digit switching was confined to calls handled by operators, the possible extension of 10-digit dialing to customers was anticipated. Some added features which permit customer direct distance-dialing and expand the usefulness of this system in certain tandem and toll applications are described in the following.

TEN-DIGIT DIALING FOR NO. 5 CROSSBAR CUSTOMERS

Late in 1951, a trial permitting customers to dial distance calls to points throughout the nation was introduced in the Englewood, N. J., No. 5 crossbar office. By the end of 1955 about 450,000 customers served by over 50 No. 5 crossbar offices were able to dial calls to 17 of the national areas[5] which include about one-third of the total Bell System telephones in the United States.

Since the No. 5 crossbar system was already designed to handle 10-digit operator calls, similar features were made available for customer-dialed calls. Also, facilities for handling three additional digits were added to the accounting equipment.[6]

FOREIGN AREA TRANSLATOR[7]

On calls to other numbering areas the marker normally recognizes only the area code (XOX or XIX where X represents any value from 2 to 9) to determine the routing. Thus, all calls to a given area may be routed over only a single tandem or toll trunk group. This restriction may result in indirect routing and inefficient use of outside plant. With the introduction of foreign area translation, the area code enables the markers to obtain access to a translator representing a particular called area, thus permitting 6-digit translation; refer to Fig. 6.

The first three digits of all calls which reach a marker are translated in the marker by a relay tree circuit.[8] Through the relay tree a code point is isolated for each three digits and is normally connected to a route relay for directing the course of that call. In the case of XOX or XIX area code digits, the code point may be wired to a connector which selects a foreign area translator serving three areas. The code point also indicates which of three areas is called. The next three digits (office code) are then carried through the connector into a relay tree in the foreign-area translator. This again isolates a particular code point for each of the office codes. This code point is cross-connectable in the translator in such a manner that one of 100 foreign-area code points is indicated to the marker. These 100 code points are now connectable in the marker to appropriate route relays for routing the call over any desired trunk group. This permits calls to be routed through more than one tandem or toll center in another area, or over direct trunks to the local offices in the other area. One translator frame extends this

service to one, two, or three foreign areas and two of these frames will care for a maximum of six foreign areas. For safety reasons each frame is arranged with duplicate translators. The foreign-area translator frame is shown in Fig. 7.

The East Liverpool office in Ohio has been chosen to illustrate this feature. As indicated in Fig. 8, the East Liverpool office is located at the boundary of three states, Ohio, Pennsylvania, and West Virginia, serving customers in all three states. Although customers served by this office actually reside in three different numbering plan areas, they are all considered to be in the Ohio 216 area, or their "home" area.

It will be noted that there is more than one route into adjacent numbering areas. About 40 community dial offices and tributaries are reached through Columbus in the Ohio 614 area, and some eight or ten tributaries are reached through Steubenville. In the Pennsylvania 412 area there are trunk groups to Rochester and Pittsburgh. Rochester is another No. 5 crossbar office, while trunks to Pittsburgh handle customer-dialed traffic to Pittsburgh offices and through traffic to New York, Philadelphia, Washington, Chicago, Detroit, and other cities. There are, of course, other routes into these areas not shown in Fig. 8. Both local customers' calls and calls originated by customers or operators at distant points which are switched through East Liverpool will utilize the foreign-area translator.

TANDEM SCREENING

When the No. 5 crossbar system serves as a tandem switching point for surrounding community dial and step-by-step offices, means must be provided to limit the direct-dialing access of these offices. Unlike common control systems, such offices are not readily adaptable to making this discrimination at the originating office, and therefore it must be made at the tandem point. This is referred to as tandem screening.

Fredericksburg, Va., is a typical case in point; see Fig. 9. Here there are five small step-by-step offices using the No. 5 crossbar office at Fredericksburg as a tandem point. Customers in all five are permitted to dial Fredericksburg numbers. Chancellor No. 1 and Chancellor No. 2 customers may also dial Spotsylvania numbers, and vice versa. On the other hand, Hartwood and Stafford customers may dial each other but are not permitted to dial beyond Fredericksburg. This is accomplished by providing class signals in the incoming trunk circuits from such offices. These signals are passed through the incoming link and incoming register to the marker where class of service distinction is made so that calls coming in over one group of trunks are extended only to certain offices. Facilities have been made available for providing as many as five screening patterns.

CODE CONVERSION

Code conversion is another feature originally made necessary by the existence of the step-by-step system in the switching network. However, new uses are being found for it. To illustrate the need for arbitrary codes see Fig. 10. Suppose an operator in one toll center

wishes to place a call to a customer in office *A* of another toll center reached through a step-by-step intertoll train. The incoming trunk from the originating operator terminates in an intertoll first selector. Levels 2 to 9 of this selector are used to reach numbers in the local step-by-step office. Levels 1 and 0 are available for through switching. It is common practice to use level 1 for tributaries and level 0 for reaching other toll centers. The operator therefore must prefix a code to the called customer's number in order properly to actuate the switches at the tandem point. From one to three arbitrary digits may be required, depending upon the number of points to be reached. For calls to office *A*, the operator would prefix *14* followed by the customer's number. On the other hand, to reach office *B* through the tandem community dial office requires an additional digit. Thus, the operator would dial *17* to get through the toll center switches, and *6* to get through the tandem community dial office, followed by the customer's number.

The practice of establishing routes utilizing arbitrary codes is satisfactory as long as operators do the dialing since they can readily check routing bulletins. However, when customers do the dialing, routing bulletins would not be practical. Several rather extensive intertoll dialing networks based on the use of arbitrary codes have already been established. For customer dialing, all offices will be reached on a 2 to 5 numbering basis, each office having a standard ABX office code followed by four numerics. Rearranging switch multiples to use the standard office codes instead of arbitrary codes would be prohibitively expensive. Since this network, based on arbitrary codes, has already been established for operator dialing, it appears reasonable to provide means for code conversion at the last common control entry point into the arbitrary code network.

Code conversion is actually a combination of digit deletion and digit prefixing. The No. 5 crossbar system has therefore been arranged to prefix one, two, or three arbitrary digits ahead of the digits received. In addition, from one to six of the digits already dialed may be deleted. This means that the outgoing dial pulse sender may outpulse the prefixed arbitrary digits and then skip any or all of the following six digits, outpulsing the remainder. Thus, by prefixing three digits and deleting the next three, complete code conversion is accomplished. Sometimes, the second or third digit of the standard code will be suitable, providing the first or second digits are changed.

Fig. 11 illustrates an application of this feature. Bismark, N. D., is a primary center and is equipped with No. 5 crossbar. Local customers, and operators in other toll centers, will reach offices through Bismark No. 5 crossbar by dialing the standard ABX office codes. The No. 5 crossbar office will convert these ABX codes into the arbitrary codes required for switching through intermediate step-by-step points. A call to Bottineau requires an arbitrary *154* to get through the Minot step-by-step primary center. Calls to Ashley require an arbitrary *7* to get through the tandom community dial office at Wishek. There are several others but this suffices to illustrate the principle.

While not so apparent, the need for being able to prefix up to three digits on a multifrequency basis may still be quite common; see Fig. 12. Suppose a customer in office *A* makes a call to office *B* in his home area; he will dial *ABX-1234*. If the direct trunk group to office *B* is busy, an alternate route through a tandem office in the adjacent area may be used. In this case it would be necessary to prefix the home area code ahead of the ABX office code in order to inform the tandem switching equipment that it must route the call back into the adjacent area. In this case the area and office codes are deleted at the tandem point, since there are direct trunks from the tandem to the completing office.

General System Improvements

In addition to the new switching features already described, the No. 5 crossbar system has been redesigned to make use of available new apparatus components, and to incorporate improved circuit and equipment designs, as the wire spring general-purpose relay, the wire spring multicontact relay, the dry reed relay, and the transistor. The general-purpose, multicontact, and reed relays are illustrated in Figs. 13 through 15.

In circuit and equipment redesign it was necessary to make new units compatible with older units so that both old and new units may function together in the same office. This was accomplished by making electrical appearance of the unit from the outside similar to that of the replaced unit, although the inner workings of the units and the layout and cabling were radically changed.

Vol. 7
Pt. 1
1956

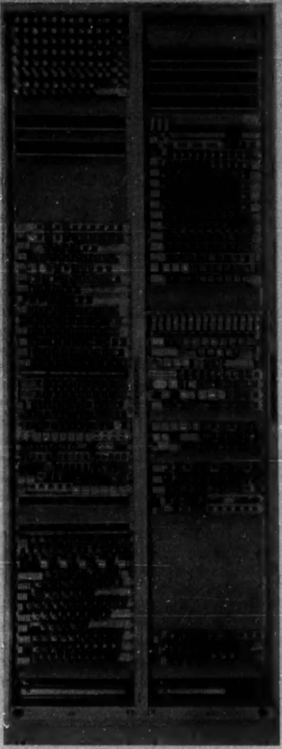

Fig. 16. The old dial tone marker

Typical Redesigns

A few typical redesigns of large, medium, and small units will be described. Figs. 16 and 17 show the old and new dial tone markers. A comparison of these two markers is shown in Table I.

Figs. 18 and 19 show the old and new originating register frames. The circuit has been redesigned to eliminate 14 of the general-purpose relays. In addition, the dry-reed type of relay has been substituted for the more conventional flat-type. A dry-reed relay package containing five coils each actuating two contacts replaces five of the older relays, and occupies a space not much larger than one of its predecessors. This permits eight registers to be mounted on a 2-bay frame which accommodated only five of the older variety. The redesign reduces the current drain by about 35% (per cent).

One of the many small redesigned units is shown with the replaced unit in Fig. 20. This is one of the widely used incoming trunk circuits. The older arrangement mounts two circuits on a 3-plate unit 6 inches high, whereas the new unit mounts one circuit on a single plate 2 inches high. This could be done partly because the wire spring slow-release relays need not have the protecting space required by the older relays to reduce magnetic interference, and partly because two relays (approximately 20% of the total relays) have been eliminated in the redesign. The functions of these relays are performed by the redesigned ringing selection switch at a small increase in its price. The space saving is 33%, and the current drain saving about 15%. While the amount of saving for each unit is small, the aggregate saving is very large, because there are hundreds of such units in each central office. In the over-all redesign, the floor area requirements for the larger offices were reduced by almost 20%.

Transistor Multifrequency Supply

A new transistor multifrequency supply circuit[9] has been standardized for the No. 5 crossbar senders. One supply circuit will be provided in each multifrequency sender. Each supply circuit has six transistor oscillators, one for each of the frequencies used in the multifrequency signalling system. Since transistors require no warm-up time, the oscillators are ready for instant use when the sender is selected. Also, the constant current drain required by vacuum-tube oscillators is not needed. This oscillator unit is omitted from the senders, if the large vacuum-tube type of common supply is required for other equipments in the same building.

New Maintenance Features

To reduce maintenance efforts and to provide better service, the maintenance facilities have been improved, and additions made. Some of the more interesting facilities are described in the following.

Automatic Progression Trunk Test Circuit[10]

Testing of trunk circuits in No. 5 crossbar offices has been accomplished by manual operation of keys to select the desired circuit and to program the test. It was soon evident that a labor-saving automatic test circuit would be economical in the larger offices. Such a test circuit has been designed for control by a perforated teletypewriter tape. For each trunk

Fig. 17. The new dial tone marker

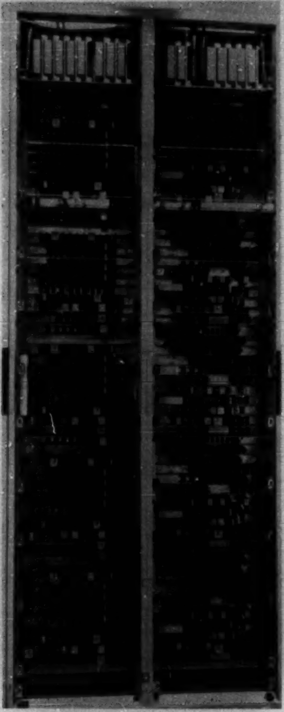

Fig. 18 (above left). The old originating register frame (five registers per frame)

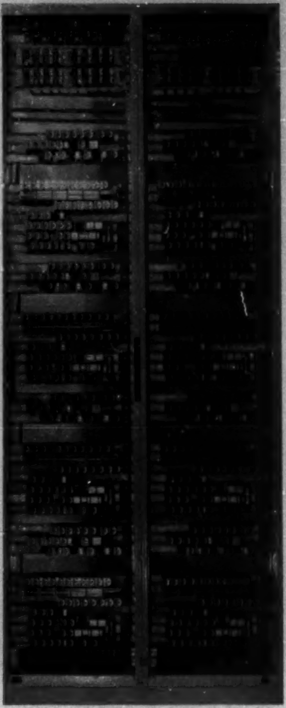

Fig. 19 (above right). The new originating register frame (eight registers per frame)

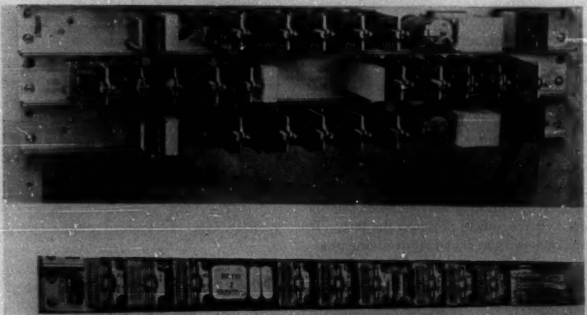
Fig. 20 (below). Old and new incoming trunk circuit units



circuit to be tested, there are 12 lines of data perforated on the tape. These contain:

1. The location of the trunk circuit on the switches.
2. The program of tests to be applied.
3. Office code and numerical digits for the test call.

The machine reads the data, causes the switching system to connect the test circuit to the trunk circuit, and applies the tests. Failures are reported to the maintenance force by means of visual and audible alarms.

A library of tapes is provided, so that different testing programs may be used on successive days. The tapes are provided in duplicate pairs, so that if one of a pair is damaged or destroyed, its mate will be available for use. The first use, of course, is to perforate automatically another mate tape, so that a pair may be always available.

The original tapes are made at the central office by operating keys on the test frame to represent the data for one trunk circuit. These data are then perforated on the tape. The keys are then set manually for the next trunk circuit, and the tape perforated, etc. This is a slow manual process but is seldom repeated.

With this arrangement the maintenance force can start a test of the trunk circuits which will continue without attention until trouble is encountered. This, of course, saves a substantial amount of maintenance effort in the larger offices.

AUTOMATIC LINE INSULATION TEST CIRCUIT[11]

Another interesting maintenance device which has been standardized for No. 5 crossbar (and some other systems) is the automatic line insulation test circuit. This circuit checks the insulation resistance of the wires reaching out to the customer premises, and provides a typed report at the test center of trouble or incipient trouble.

This outside plant of the telephone system deteriorates because of age, weather, and other factors, which causes a reduction in the insulation resistance between

the conductors of a pair, and between these conductors and neighboring pairs in a cable, or between the conductors and ground. These conditions may be caused by moisture entering cable sheath breaks, dust on cable terminal face plates, tree branches, dirt on insulators of open-wire lines, and by breaks in the covering of drop wires. In dry weather these defects do not affect service. However, if not corrected, a sudden rainy period will put a number of lines out of service because of low insulation resistance. This is not only bad from a service standpoint, but it may impose a serious overload on the maintenance people, possibly at night, or on a nonworking day.

To find these incipient troubles before they affect service, and so that they can be repaired during regular working hours, the automatic line insulation testing equipment is being installed in most of the new No. 5 crossbar offices, and is being added in many of the existing offices. It can be started either manually or by means of a program clock at the central office, or manually from a remote test bureau. The report of the failures is automatically teletyped to the test bureau, and the details of the test record appear on a printed page, a sample of which is shown in Fig. 21.

The clock is used principally to start a test in the early morning when low temperature has caused the cable to "breathe in" damp air through sheath breaks. This reduces insulation resistance of conductors near the break. The control from the remote test bureau, is used principally to start the test when sudden weather changes affect the outside plant. The rate of testing is 10,000 to 12,000 lines per hour so that all lines in an office can be tested during a short rainy period. The data at the test bureau are analyzed, and further tests and inspections are made of suspected parts of the plant.

The test circuit has a nongrounded d-c source to detect leaks between the conductors of a pair, and a grounded source to find leaks to ground from either conductor. It is also arranged to test for leaks to other conductors in the same cable. These other conductors are usually connected to a negative 48-volt source at the central office; the leaks can therefore be distinguished from leaks to ground. A filter is provided to prevent interference from 25- and 60-cycle earth potentials so that a-c earth potentials will not exaggerate leakage to ground. The circuit is capable of detecting insulation resistance as high as 10 megohms, but is usually used at 2 megohms or less.

Fig. 22 shows intraoffice trunk circuits. Fig. 23 shows the new fuse panel, which will be smaller than its predecessor. It has a dead front, and better appearance; fuses can be replaced without tools, and there can be no flashover between fuses.

Fig. 24 shows a typical crossbar switch. The armatures of the newest crossbar switch have damping cones which deflect the select finger out of its vertical travel path. The finger strikes the edges of the actuating cards and loses its energy quickly. Fifteen milliseconds of marker work time are saved if all switches in the office are provided with damping cones. This is because the marker does not have to wait as long before reoperating the hold magnet which has just released the select finger on a previous call.

In this paper it has been possible to cover only the highlights of the recent changes in the design of the No. 5 crossbar system. In some cases the more interesting or more important items were chosen for discussion. In other cases a few items, which are typical of many others, were described.

Capability of Sealed Contact Relays

O. M. HOVGAARD
NONMEMBER AIEE

A CIRCUIT designer contemplating the use of a relay must consider its operating characteristics and the reliability of its contacting function. The electric erosion causing contact wear gives rise to contact surface conditions permitting contact failure to open a circuit caused by locking; particularly in talking circuits, reliability can be further impaired by the operating environment which may contain corrosive elements, organic vapors, or mobile dirt, all of which increase the probability of failure to give contact closure. Unfortunately, the incidence of these factors affecting reliability is not predictable with respect to time or place. The considerations involved are not unlike those associated with electron tubes and transistors. Because of the growth in the complexity of electric switching systems increasing emphasis is placed upon the elimination of factors affecting component reliability. In the Bell System one means to achieve improved reliability has been the development of sealed contacts. Two types have reached application, both providing encapsulation to free contacts from the effects of environment; one type, in addition, circumvents the effects of electric erosion by employing liquid contact surfaces. The development of sealed contacts and relays using such contacts has been described elsewhere;[1–4] the purpose of this paper is to consider some of their characteristics from the standpoint of application.

Fig. 1 shows three forms which these contacts have assumed. *A* is the simple encapsulation of a more or less conventional contact; *B* and *C* are forms employing mercury-wetted contact surfaces. The basic principle of operation of all three designs is that of overlapping cantilevers of magnetic material separated by a small gap. When the contact is surrounded by an operating winding carrying current, the ends of the cantilevers are drawn together to form the contact pair controlling a load circuit.

Operating Characteristics

For the type of sealed contact under consideration, the operating characteristics are defined in terms of its behavior when it is associated with a simple air-core coil of specified dimensions. The characteristics are expressed in terms of that value of ampere-turns at which the contact will just close and that lower value at which it will just reopen.

In the course of development, the designer will have established the desired mean values of these characteristics. Through a visualization of the process to be used in manufacture and by laboratory experiments, he will also have determined the attainable standard deviations for these characteristics and a measure of the closeness within which the mean values can be held. Upon these considerations he will have specified the desired mean values and the limits with respect to these within which the manufactured product must be held.

Relay Design

While for manufacturing purposes the characteristics of the sealed contact are defined in terms of the contact behavior in an air-core coil, actual relay designs usually provide ferromagnetic paths to increase electromechanical efficiency and to decrease magnetic coupling to nearby circuit components. More than one contact may be used within the same operating coil. The operating characteristics which can be ascribed to a specific design will depend upon the number of contacts, the characteristics of the contacts and their relative positions within the coil, the reproducibility of the magnetic circuit and coil turns, etc.

For a given relay design, the spread in the sealed contact operating characteristics and the combination and placement of the contacts in a specific relay are the main factors causing a spread in the relay operating characteristics about their mean values. Laboratory studies make it possible to estimate the magnitude of these variables and to arrive at tolerances which the relays must meet in manufacture.

What should the relay tolerances mean to the circuit designer and how may he use them? Since sealed contacts are not adjustable after manufacture, the answer depends on how the manufacturer has used the limits given in the specification.

Suppose that the upper limit of a relay design requires a current I to give contact closure, and that there is no information concerning the distribution of this relay operating characteristic. The relay is to be used in a circuit subject to voltage and temperature variations. Let it be assumed that nothing is known about the distribution of these variables with time but that their maximum values can be stated. The coincidence of the highest temperature condition and lowest voltage supply, barring other variables, is called the worst circuit condition since it results in the minimum value of current for the operation of the relay. How shall this worst circuit current be related to the value I defined in the foregoing?

Lacking information to the contrary about the relay characteristic, the circuit designer can only assume that in manufacture the upper value of required current I is as permissible as any other value within the stated tolerance and that he

O. M. Hovgaard is with the Bell Telephone Laboratories, Inc., New York, N. Y.

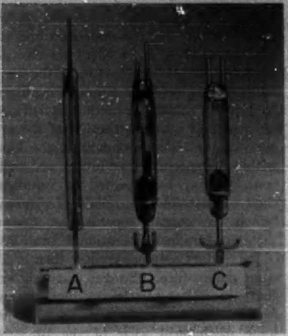

Fig. 1. Typical sealed contacts

will have to provide a margin between it and the worst circuit current. The size of the margin represents the designer's judgment of the reliability of the facts available to him and maybe also his estimate of the probability of occurrence of the worst circuit current.

However, if the designer knows that the manufacturer has designed his process so that the specified quality characteristic meets the standard deviation and maintenance of mean value visualized in the specification and if he can be assured that the manufacturer maintains the characteristic in statistical control at the desired level, he is then entitled to inference with respect to the distribution of the quality characteristic within the stated limits. For purposes of illustration, assume that the distribution of the characteristic is centered and can be represented by a normal distribution and that the manufacturing limits represent four standard deviations. If then the worst circuit current were placed at the upper limit for the relay I, the probability of a failure under worst circuit conditions would be about one in 30,000. This, combined with the likelihood of occurrence of the worst circuit condition, might be more conservative than is required. Circuit power could be conserved by placing the worst circuit condition at, say, $2^{1}/_{3}$ standard deviations from the central value of the operate characteristic and then the probability of relay failure under worst circuit conditions would be about one chance in a hundred. If this risk is acceptable, it becomes possible to approve a circuit design which might not be possible if there were not assurance that the relay characteristic had a normal distribution.

As a goal, if the circuit variables and component characteristics are in fact in statistical control at the desired levels, the designer can determine circuit performance and reliability on a statistical basis. This will permit him to approve smaller circuit margins than would otherwise be possible, thereby obtaining more complete utilization of component capability as well as improved circuit efficiency.

Contact Behavior

The operating characteristics discussed are the result of design and process decisions concerning dimensions and tolerances and, thus, are subject to manufacturing control. The behavior of the contact with respect to its electric load as well as its reliability in use result from design decisions concerning contact materials, purity and kind of selected gaseous environment, contact surface preparation, cleanliness, etc. The relationships between these factors and the contact life and reliability are not as well understood as are those affecting the operating characteristics and, therefore, life and reliability are not yet subject to manufacturing control to the same degree as are the operating characteristics.

Consider first the behavior of type-*A* contacts. Life test studies with electric loads of various magnitude and kind show that, like other contacts having solid surfaces, they suffer erosion which becomes more violent as the loads increase. This erosion progressively alters the surface geometry causing build-ups on one contact and corresponding pits on the other. Unlike ordinary contacts the by-products of erosion are magnetic and tend to collect in the gap under the influence of the operating flux. As a result, there are at least two mechanisms which can cause contact failure. In one, build-ups and pits may reach the right configuration to cause mechanical locking which, if it cannot be overcome by the available reed-restoring forces, prevents opening of the contact. In the other, the by-products of erosion, which may be either loose or fastened to one reed, can form chains of particles capable of bridging the space between the unoperated reeds which then will be electrically closed. As a failure mechanism, locks are several times as numerous as bridges, but the relative expectation of their occurrence appears unrelated to the length of time that the contact has been in use.

In general, the behavior with load is quite similar to that observed with other hard-surface contacts. As the load increases, the life of the contact gets shorter. However, for the upper load level of which these contacts are capable, the rate of decrease of life with increasing load is not as great as that observed with ordinary contacts. This may be because of the capture of magnetic erosion by-products in the operating gap. For part of the operations, contact will be established through such particles and, as a result,

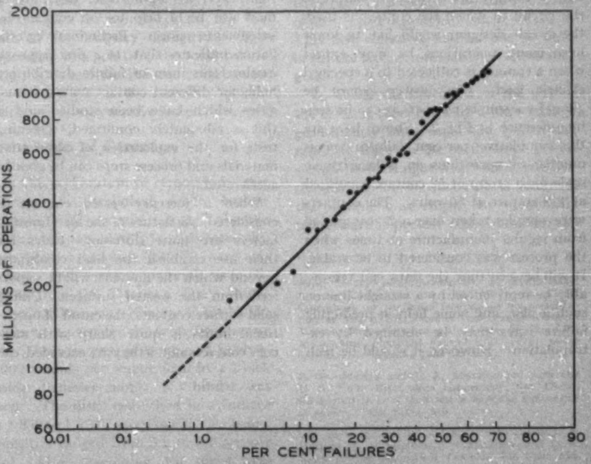

Fig. 2. Life study of type-A contacts

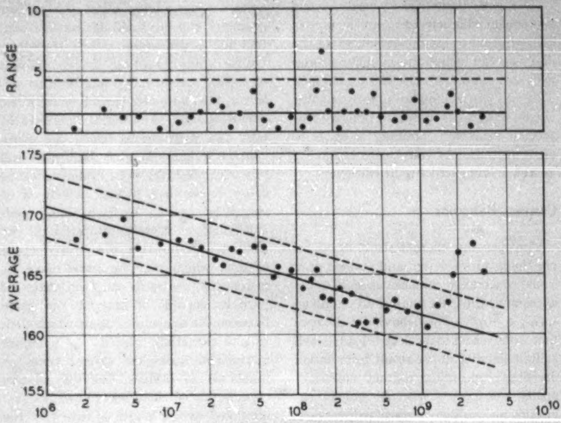

Fig. 3. Stability of type-B contact with life

they may absorb a part of the erosion. These particles also, in general, tend to move at each operation and, by spreading the erosion over a greater portion of the contacting area, may effectively increase the life of the contact.

As might be expected from the complicated behavior described, observations of laboratory life tests show an enormous spread in the life obtained from nominally identical sealed contacts. Since the end of contact life means the failure of the circuit in which the contact is used, the circuit designer would like to know how many operations he may expect when a contact is subjected to a specified electric load. The answer cannot be given by a simple number, as can be seen by reference to Fig. 2. Shown here are the cumulative per-cent failures versus number of operations on a logarithmic scale for a group of 52 contacts operated at 1/8 ampere at 50 volts. The contacts were samples taken over a 2-year period from regular manufacture at times when the process was considered to be stable. It will be seen that the data can reasonably be represented by a straight line on such a plot, and some help in predicting failure rates may be obtained by extrapolation. However, it should be realized that this technique involves some risks. In the first place, the confidence limits are rather wide with so small a sample and, secondly, another sample might yield a different slope. Also there can be no assurance that there is not some other mechanism which could cause early failures in excess of those predicted. It may not have been possible to detect such a cause in so small a sample. The linear relationship, which represents a log-normal distribution, may also be of help to the contact development engineer. Preliminary investigation indicates that, to a first approximation, this form of failure distribution holds for different contact materials and gases which have been studied and if this is adequately confirmed, screening tests for the exploration of alternative materials and process steps can be greatly accelerated.

When a mercury-wetted contact is considered, the nature of the load limiting factors are quite different. Rules for their use establish the load conditions beyond which the mercury will be vaporized from the wetted surfaces. Unlike solid-surface contacts, the cutoff of operational limits is quite sharp with mercury contacts and, if they are exceeded, the contact life is drastically reduced. However, within the recommended operating range, there is in effect no electric erosion since, at each operation, the mercury film is restored through capillary feed paths under the action of surface tension. As a result, the life of a mercury contact is independent of the load within the specified load limits, and such contacts may be expected to maintain their contact function reliably for many billions of contact operations. Under these conditions, operational stability of the contact assumes greater than ordinary importance. Studies have shown that, in spite of the cushioning effects of liquid contact surfaces, there is some mechanical wear of the surfaces supporting the mercury film, and the pretensioned armature spring may lose some of its initial force because of fatigue. These factors cause slow systematic changes in the operating characteristics. Fig. 3 shows a control chart plot of the operate value of two mercury-wetted contacts.[5] These charts are for the successive averages and range of the two contacts. It is seen that, after 2 billion operations, the characteristics studied went out of control. Although after 3 billion operations the observed operate values were still not greatly different from their initial values, and the contacting function was unimpaired, it was no longer possible to predict operational performance, and on this basis, the useful life must be considered ended. This illustrates the application of a quality control chart as a means for defining life.

In summary, experience with sealed contact relays indicates that statistical methods are useful not only during development and manufacture but also promise to be an effective means for describing their attributes.

Investigations Concerning Polarization in Barium Titanate Ceramics

G. W. MARKS
NONMEMBER AIEE

D. L. WAIDELICH
FELLOW AIEE

L. A. MONSON
NONMEMBER AIEE

Synopsis: Considerable information may be obtained concerning polarization in barium titanate ceramics by a careful analysis of hysteresis loops. Mathematically it is shown that both symmetrical and unsymmetrical loops, the latter being characteristic of polarized specimens, can be represented best by a Fourier series. It was found that direct voltage and even harmonic components are present in the unsymmetrical loops. The per-cent second harmonic and the electromechanical coupling coefficient both rise with increasing depolarizing voltage and reach a maximum value at approximately 15,000 volts per cm (centimeter). The measurement of the second harmonic is possible even when the activity is so small that measurement of the coupling coefficient becomes very inaccurate or impossible. The addition of calcium titanate in small percentages markedly raises the coercive force but lowers the spontaneous and remanent polarization in the range from 0 to 80 C (degrees centigrade). However, it does not have marked effect between the latter temperature and the Curie point. It was found from studies of the discharge currents on depolarizing specimens by sudden immersion in hot oil that the polarization observed from the discharge curves is essentially the same as the remanent polarization determined from oscillograms of saturated hysteresis loops.

IN RECENT years, many investigations have been made in attempts to elucidate the polarization phenomena of ferroelectrics because of their engineering applications. Of particular interest have been those concerning barium titanate and related compounds having the perovskite structure. The polarization of polydomain ceramic ferroelectrics by the application of an external field consists, in general, of the following processes: 1. the direction of polarization in any crystallite tends to orient in the direction of the applied field, 2. the polarization in the domains increases in magnitude, and 3. the relative volume occupied by different domains changes primarily by growth in the forward direction; sidewise motion of 180 degrees side walls hardly ever occurs.[1,2] This includes the growth of the induced polarization, much the same linear process as in ordinary dielectrics.

Among the lag and fatigue effects which characterize ferroelectrics is the hysteresis loop. Much knowledge concerning polarization and related properties may be obtained from a careful study of these loops as recorded by means of a cathode-ray oscillograph.[3–12] However, the rate of change of the field for a 60 cycle-per-second hysteresis loop is so rapid that long-time relaxation phenomena which contribute to the polarization are not observed and thus somewhat lower polarization values than the possible maxima are obtained. Recently, by the use of a high-voltage switching and integrating circuit, the relationship between total and remanent polarization to the applied field and applied field duration has been determined at constant temperature for barium titanate ceramics.[13]

For ready reference a representative hysteresis loop for a polycrystalline multidomain ferroelectric is shown in Fig. 1. The variation of polarization P with field strength E is depicted. The spontaneous polarization P_s is obtained by extrapolation of the saturated linear portion of the loop to zero field strength. Note that beyond E, where the linearity commences, the increase in polarization is induced polarization only. Except for the fact that this extrapolated portion does not pass through the origin, it is the same as for ordinary dielectrics. Corresponding to a point E_2, the total polarization is P_t and the induced polarization $P_i = P_t - P_s$. P_r is the remanent polarization; E_c is the coercive force.

Preparation of Ceramics

In the preparation of ceramics for this investigation, technical grade barium titanate, 97% (per cent); technical grade calcium titanate (96.5%); and chemically pure barium titanate (99.7%) were employed (All ceramic materials were obtained from the Titanium Alloy Manufacturing Company, Niagara Falls, N. Y.) Disks were prepared for firing by pressing 6 to 10 gm (grams) of sample at 5,000 to 8,000 pounds per square inch in a 1-inch inside diameter mold. No binder was used. The disks were fired in a furnace at 1,350 to 1,370 C from one to two hours. Densities ranged from 5.3 to 5.6 gm per cm^3. After machining, the disks were foiled with silver.

Circuit for Recording Hysteresis Loops

For the study of hysteresis loops, in general, previous workers have used a parallel-connected resistance-capacitance voltage divider. However, it was found that a circuit utilizing capacitance voltage dividers only was more suitable for the present purpose. A diagram of this circuit is shown in Fig. 2. Maximum secondary peak voltages of approximately 25 kv per cm could be impressed. Secondary voltages were controlled by means of a Variac. The capacitance voltage divider, consisting of C_1 and C_2, resulted in a voltage across C_2 directly proportional to the alternating voltage across the ceramic and this voltage was applied to the horizontal plates of the oscillograph. This voltage is proportional to the electric field E applied to the ceramic. The capacitance of C_2 being much larger than that of C_1, its effect on the voltage across C_1 may be neglected. Thus, the field intensity across the ceramic is $E = C_1V_2/C_1d$. V_2 is the voltage across C_2 and d is the thickness of the ceramic. C_3 integrates the instantaneous polarizing current i which flows into the ceramic to give a voltage V_3 which is proportional to the polarization P. The capacitance C_4 of the ferroelectric is extremely high compared to that of C_3. V_3 is then the voltage applied to the vertical plates of the oscilloscope and so the hysteresis loop is observed.

If P is the polarization in coulombs per cm^2 and a is the area in cm^2 of an electrode face, then $i = a(dP/dt)$ and $P = (1/a)\int idt$. Since $V_3 = 1/C_3 \int idt$, $P = C_3V_3/a$. This last equation enables one to calibrate the axis of ordinates of an oscillogram.

To check the operation of the circuit the ceramic is replaced by a high-voltage good-quality mica capacitor. Then the resulting trace on the oscilloscope screen should be a straight line with a positive slope when the vertical gain is zero. If the pattern is an ellipse, an undesirable phase shift is present somewhere in the

circuit or in the oscilloscope, and this should be eliminated.

Application of Fourier Series

With varying degrees of success, attempts have been made by a number of investigators to fit various mathematical equations to the magnetization curve of ferromagnetics. Press[11] and Lewis[13] have suggested the use of Fourier series, and in the analysis of the ferroelectric hysteresis loops of barium titanate such a procedure has been used. Accordingly, if

$$x=\left(\frac{E}{E_m}\right)\sin \omega t \qquad (1)$$

where E_m is the maximum electric field applied to the specimen and ω is the angular frequency of the sinusoidal variation producing the loop, then

$$y=\frac{P}{P_m}=a_0+a_1\cos \omega t+a_2\cos 2\omega t+\ldots+ b_1\sin \omega t+b_2\sin 2\omega t+\ldots \qquad (2)$$

where P_m is the maximum polarization and the a's and b's are constants for a given hysteresis loop. (It is perhaps well to point out that for barium titanate the dielectric constant is so large that the displacement $D\approx 4\pi P$ in centimeter-gram-second units. D and P can be used interchangeably if meter-kilogram-second units are used.) If the parameter t is eliminated between equations 1 and 2

$$y=(A_0+A_1x+A_2x^2+A_3x^3+\ldots)\pm (1-x^2)^{\frac{1}{2}}(B_0+B_1x+B_2x^2+ B_3x^3+\ldots) \qquad (3)$$

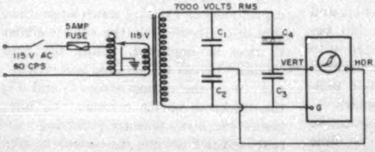

Fig. 2. Circuit for studying hysteresis loop of ferroelectrics. C_1 0.003 μf, 25 kv; C_2 2.0μf, 600 volts; C_3 7.2 μf, 600 volts; C_4 ferroelectric

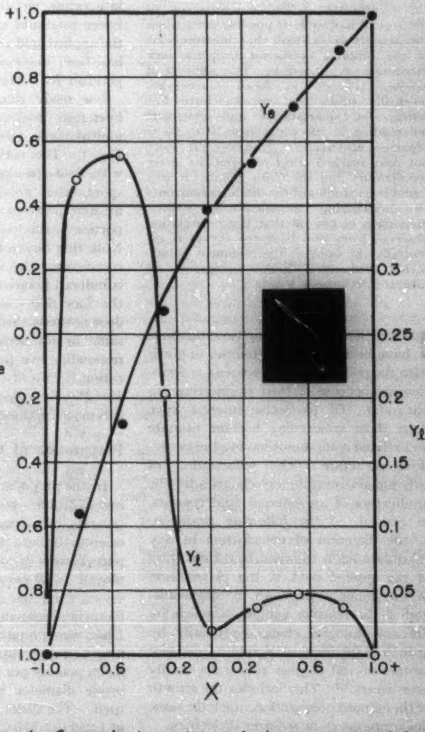

Fig. 4. Curves showing variation of electrization y_e and loss y_l with field strength ration $x=E/E_m$. Data calculated from measurements on hysteresis loop (insert) for technical grade ceramic disk of polarized BaTiO₃. E_m=9700 volts per cm. Calibration cross not shown

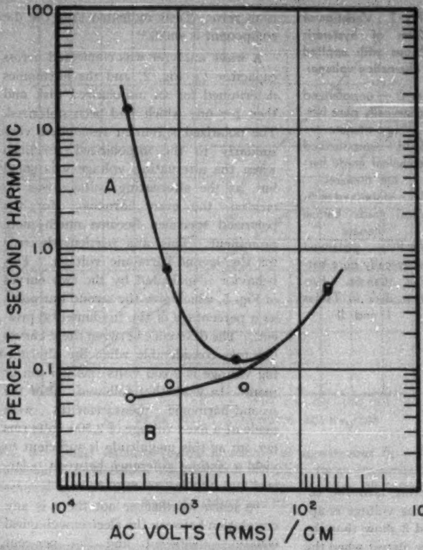

Fig. 5. Per-cent second harmonic (percentage of the fundamental voltage present) as function of voltage applied to ceramic for: A—polarized, and B—unpolarized barium titanate disks

where

$A_0 = a_0 + a_2 + a_4 + a_6 + \ldots$
$A_1 = b_1 + 3b_3 + 5b_5 + 7b_7 + \ldots$
$A_2 = -2a_2 - 8a_4 - 18a_6 - 32a_8 - \ldots$
$A_3 = 4b_3 - 20b_5 - \ldots$, etc.

The ± signs in equation 3 correspond to the upper and lower parts of a given hysteresis loop respectively. It is possible to eliminate the ± signs entirely by squaring equation 3 to obtain

$$y^2 - 2y(A_0 + A_1x + A_2x^2 + \ldots) + (D_0 + D_1x + D_2x^2 + D_3x^3 + \ldots) = 0 \qquad (4)$$

in which

$$\Sigma D_n x^n \equiv (\Sigma A_m x^m)^2 - (1 - x^2)(\Sigma B_m x^m)^2$$

Equation 4 is the equation of the entire hysteresis loop but for most purposes equation 3 is more useful.

A symmetrical hysteresis loop is one in which the origin of co-ordinates is a center of symmetry and so involves only odd functions. When this fact is utilized, the even A's and odd B's are zero so that

$$y = (A_1x + A_3x^3 + A_5x^5 + \ldots) \pm (1 - x^2)^{\frac{1}{2}}(B_0 + B_2x^2 + B_4x^4 + \ldots) \qquad (5)$$

Let y_a represent the upper portion and y_b the lower portion of the symmetrical loop, then

$$(A_1x + A_3x^3 + \ldots) = \tfrac{1}{2}(y_a + y_b) = y_e \qquad (6)$$

and

$$(1 - x^2)^{\frac{1}{2}}(B_0 + B_2x^2 + \ldots) = \tfrac{1}{2}(y_a - y_b) = y_l \qquad (7)$$

where y_e represents the electrization curve (similar to the magnetization curve of ferromagnetism) and y_l represents the loss curve corresponding to the loss as shown by the area of the hysteresis loop.

As an illustration of the procedure to be employed, measurements were first made on the symmetrical hysteresis loop shown in the insert of Fig. 3. Values of y_e and y_l were then calculated and the resulting electrization and loss curves are shown in this figure. The A's of equation 6 and the B's of equation 7 may be calculated by selecting a number of points on the curves of Fig. 3, and using the number of A's and B's equal to the number of points selected. In most cases, however, the experimental curves for y_e and y_l may be fitted adequately with the use of a lesser number of constants by employing special functions such as the hyperbolic tangent or exponential functions.

Polarized specimens of ceramic barium titanate produce unsymmetrical hysteresis loops if the applied alternating voltage is sufficiently high. For an unsymmetrical loop

$$y_a = (A_0 + A_1x + A_2x^2 + \ldots) + (1 - x^2)^{\frac{1}{2}} \times (B_0 + B_1x + B_2x^2 + \ldots) \qquad (8)$$

$$y_b = (A_0 + A_1x + A_2x^2 + \ldots) - (1 - x^2)^{\frac{1}{2}} \times (B_0 + B_1x + B_2x^2 + \ldots) \qquad (9)$$

Then

$$y_e = \frac{1}{2}(y_a + y_b) = (A_0 + A_1x + A_2x^2 + \ldots) \qquad (10)$$

and

$$y_l = \frac{1}{2}(y_a - y_b) = (1 - x^2)^{\frac{1}{2}} \times (B_0 + B_1x + B_2x^2 + \ldots) \qquad (11)$$

Electrization and loss curves derived from the hysteresis loop of a polarized disk of barium titanate are shown in the insert of Fig. 4. The upper part of the hysteresis loop is the saturated part, i.e., the direction of polarization and the direction of the applied a-c field are then the same. The larger lower part of the hysteresis loop occurs when the a-c voltage is opposite in direction to that of polarization

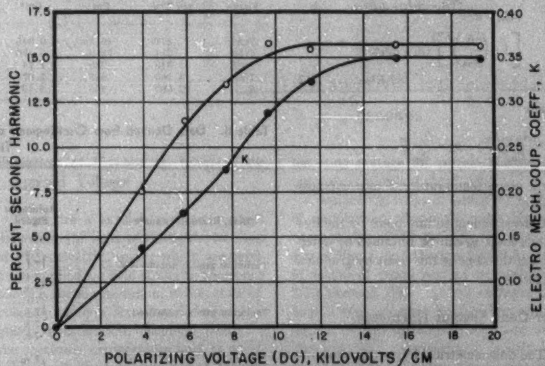

Fig. 6. Rise of percentage second harmonic present and of electromechanical coupling coefficient with increase in polarizing voltage for barium titanate disk

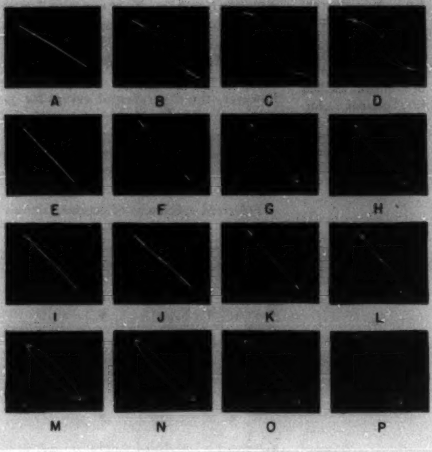

Fig. 7. Variation of form of hysteresis loops with applied alternating voltage:

A–D — unpolarized chemically pure barium titanate
E–H — unpolarized technical grade barium titanate
I–L—polarized technical grade barium titanate
M–P — polarized chemically pure barium titanate. Further data in Tables I and II

The *A*'s of equation 10 and the *B*'s of equation 11 may be determined by selecting a sufficient number of points from Fig. 4. The unsymmetrical shapes of the y_c and y_t curves show that the differential permittivity is larger in the unsaturated direction than it is in the polarized direction.

For theoretical work equation 6 is very useful. Once the constants for any given loop have been determined it is possible to obtain the differential susceptibility, $\eta_d = \partial P/\partial E$. From equation 3 it follows that

$$\left(\frac{\partial P}{\partial E}\right)_{T,C} = \alpha_0 + \alpha_1 E + \alpha_2 E^2 + \alpha_3 E^3 + \ldots \pm \frac{E}{(E_m - E^2)^{1/2}} (\beta_0 + \beta_1 E + \beta_2 E^2 + \ldots) \pm \left[1 - \left(\frac{E}{E_m}\right)^2\right]^{1/2} (\beta_1 + 2\beta_2 E + 3\beta_3 E^2 + \ldots) \quad (12)$$

where

$$\alpha_n = \frac{A_{n+1} P_m}{E_m^{\,n+1}}; \quad \beta_n = \frac{B_n P_m}{E_m^{\,n}}$$

for a given temperature *T* and composition *C*.

Corresponding to any point on the hysteresis loop, η_d can be obtained by determining the slope at this point by graphical methods.

Per-Cent Second Harmonic

The unsymmetrical hysteresis loops observed for polarized barium titanate suggest that direct and even harmonic voltage components may be present as a result of the charge flowing into the ceramic when an alternating voltage is applied. Equations 3 and 5 show that the even *A*'s and odd *B*'s are absent when the loop is symmetrical but are present when the loop is asymmetrical. Since the even *A*'s and odd *B*'s are sums of the amplitudes of the direct and even harmonic components, it would seem that some of these components should then be different from zero. Tests indicated that the d-c component is small.[16]

A wave analyzer was connected across capacitor C_3, Fig. 2, and the harmonics determined for an unpolarized disk and then for one which had been polarized. The polarized specimen responded very similarly to the unpolarized specimen when the alternating voltage was small but, as the alternating voltage was increased, the even harmonics for the polarized specimen became much more prominent. This was particularly true for the second-harmonic voltage. This behavior is indicated by the two curves of Fig. 5, which give the second harmonic as a percentage of the fundamental present. The difference between these curves becomes considerable when the alternating voltage is 2,000 volts rms per cm or more. In work that followed, all of the second-harmonic measurements were made at a fixed voltage of 2,500 volts rms per cm as this magnitude is sufficient to yield a distinct difference between polarized and unpolarized specimens.

To learn whether or not there is any correlation between the electromechanical coupling coefficient and the per-cent second harmonic, an initially unpolarized specimen was polarized at successively increasing direct voltages for one hour at room temperature.

After each period of polarization, the per-cent second harmonic present was

measured and the electromechanical coupling coefficient calculated from measured values of the resonant and antiresonant frequencies for the radial mode of vibration. Results are presented in Fig. 6 for the particular experimental conditions described. Both variables rise with increasing polarizing voltage and reach a maximum value at about 15×10^3 volts per cm. Above this voltage no significant improvement in polarization occurs. The per-cent second harmonic rises somewhat faster than the electromechanical coupling coefficient.

Variation of Hysteresis Loops With Applied Voltage

There are a number of factors which determine the form of the hysteresis loop of a ferroelectric, among which are maximum applied a-c field strength, frequency above a certain minimum value, state of polarization if a ferroelectric ceramic is under investigation, chemical purity of the specimen, temperature and, to a certain extent, the total number of domains present. The variation in the form of observed hysteresis loops with applied alternating voltage for certain barium titanate ceramics is shown in Fig. 7.

Consider the loops obtained for a disk of unpolarized, chemically pure barium titanate, Fig. 7(A) through (D) and insert of Fig. 3, and those obtained for one of technical grade barium titanate Fig. 7(E) through (H). At low voltages the loop is very nearly a straight line and is similar to that for an ordinary dielectric. The resultant polarization is largely induced and the domain structure is but little affected. As the voltage increases, the center of the loop expands with in-

crease in domain orientation. Notice that for the technical grade specimen of barium titanate the saturation effect is not nearly so apparent and the difference between the end and center dielectric constants is small. Also the contraction of the center of the hysteresis loop indicates that both the coercive force and the remanent polarization are relatively small. Data derived from these oscillograms are given in Tables I and II respectively. Note that the center dielectric constant, Table I, increases to very large values while the end dielectric constant changes less markedly. The average dielelectric constant P_m/E_m rises to a maximum and then declines after saturation sets in. The spontaneous and remanent polarizations and the square of the coercive force increase nearly linearly with increase in peak field strength over a wide voltage range, as shown in Figs. 8 and 9 respectively. In none of our work on ceramics did the remanent polarization reach the value of approximately 16μ coulombs per cm² measured for saturated single crystals of barium titanate.[17, 18]

The effect of prior polarization of the barium titanate on the form of the hysteresis loops is shown for a technical-grade specimen in Fig. 7 (I–L); in the insert of Fig. 4; and for a chemically pure high loss specimen in Fig. 7(M) through (P). The noticeable asymmetry in the loop does not appear until the effect of the domain orientation becomes marked which would be in the neighborhood of 3,500 peak volts per cm. For the high-loss specimen the minor axis of the ellipse has expanded considerably over that for low-loss specimens. An ellipse formed at low voltages indicates that the specimen has a relatively high loss.[4] Variation of maximum polarization and average dielectric constant with field strength are given in Table II for these last two disks.

Several specimens of chemically pure and of technical grade barium titanate were investigated and the hysteresis loops and results presented here are typical for these respective grades.

High-Temperature Depolarization

Ferroelectrics which have been polarized by a strong d-c field are readily depolarized by heating at temperatures above the Curie point. We have made certain observations concerning this depolarization process. The experimental procedure was to immerse a previously polarized specimen of ceramic barium titanate very suddenly into hot castor oil (150 C) and record the discharge current on an oscillogram. During the first 3 seconds after immersion there is a sudden and rapid loss of charge which declines nearly to zero and thereafter the current again rises and declines, the second process being much slower and taking 10 or more seconds; see Fig. 10. In some instances the discharge curve dropped below the time axis, as shown in the oscillograms of Fig. 10. The second process is due to all or any of a number of factors among which are the slow disorientation of the domain structure of the ceramic, dipole and space charge neutralization, and the electrical double-layer effect. By photographing the discharge process during the first three seconds only, the form of the initial transient can be seen more clearly; see Fig. 10. This transient may be due to the pyroelectric effect in barium titanate. If a logarithmic plot is made of this discharge current versus the time after the peak current value is reached, a straight line results, as shown in Fig. 11. This was found to be true in all cases investigated. The initial current rise, which is negatively limited by the circuit time constants is linear or very nearly so. The decline is represented empirically by the function $i=i_0\ t^{-m}$ where i is the discharge current in microamperes, t is the time in seconds, and i_0 and m are constants. The charge P_x released per unit area of disk up to time t_2 is then

$$P_x=\left(\frac{1}{2a}\right)i_1t_1+\frac{i_0}{a}\int_{t_1}^{t_2} t^{-m}dt$$

$$=\left(\frac{1}{2a}\right)i_1t_1+\frac{i_0}{a(1-m)}\,[t_2^{1-m}-t_1^{1-m}] \quad (13)$$

The time at which the current reaches its peak is t_1, and the area of one face of the disk is a. The charge resulting from the initial rise is determined from the area of the underlying triangle.

In the oscillograms of Fig. 10 it is observed that the second discharge commences before the initial transient falls to zero. The region beyond which the overlapping of the two processes becomes serious is perhaps best indicated by the fact that the logarithmic plot is then no longer linear. Thus, where P_x is to be determined for purposes of comparison the upper time limit t_2 has been taken to be that value at which the discharge current has declined to 0.1μa per cm.² Some comparative results are presented

in Table III for a barium titanate disk polarized under the various conditions given. In each instance the disk was depolarized and an oscillogram taken immediately after polarization. The exponent $-m[d \ln i/d \ln t]$ of equation 13 is very nearly constant. P_s depends on field strength and time of application up to saturation.

It is desirable to correlate, if practicable, the polarization as determined from the area under the discharge curve and one of the degrees of polarization determinable from the saturated hysteresis loop of the same ceramic disk in the unpolarized state. A series of technical grade barium titanate disks was prepared, the thickness of which after machining ranged from 0.15 to 0.5 cm. These were polarized at 16 kv per cm and discharge oscillograms taken 24 hours later. It should be recalled that polarized barium titanate only slowly declines to a more or less metastable condition. Saturated hysteresis loop oscillograms also were obtained for each disk. From the latter were determined the spontaneous polarization P_s and the remanent polarization P_r. From enlarged photographs of the discharge oscillograms, areas under the curves were determined with a planimeter. As previously mentioned, the discharge curve sometimes dropped below the time axis. The polarization calculated from the area above the time axis will be termed, the positive polarization P_0, and that positive polarization from which has been subtracted the negative polarization (corresponding to the discharge area below the time axis) will be termed the difference polarization P_t. Respective ratios P_0/P_s, P_t/P_s, P_0/P_r and P_t/P_r were then calculated and the results are plotted in Fig. 12. The curves are straight lines parallel to the axis of abscissas, showing that at least over the range investigated the thickness of the disk did not affect the results. It is observed that the ratio P_0/P_r comes nearest to unity. This seems to indicate that the polarization as determined from the discharge curves is essentially the same as the remanent polarization P_r of the saturated hysteresis loop.

Variation of Spontaneous and Remanent Polarizations, and Coercive Force With Temperature

Hulme was perhaps the first to measure the temperature variation of the spontaneous polarization of a crystal of barium titanate.[19] Later Merz investigated the spontaneous polarization in single crystals along the c axis over wide temperature ranges.[20,21] Discontinuities were found in the polarization-versus-temperature curve wherever a change in crystal class occurs.

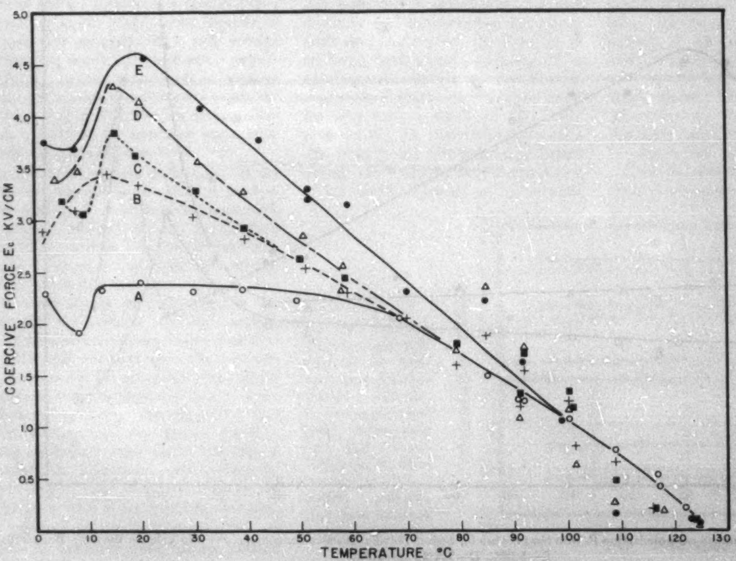

Fig. 15. Variation of coercive force with temperature for barium titanate ceramics containing: A—No calcium titanate, B—2.5%, C—5.0%, D—7.5%, E—10%

This observation is in accordance with the assumption that the spontaneous polarization is parallel to the c axis of the crystal when it is tetragonal (approximately from 0 to 120 C), parallel to a face diagonal when the crystal is orthorhombic (approximately from −80 to 0 C), and parallel to the body diagonal when the crystal is trigonal (below −80 C). Merz deduced his data from oscillograms of hysteresis loops. The spontaneous polarization remains nearly constant (8μ coulombs per cm^2) from the −80 C transition temperature down to 4.2 degrees Kelvin (K), the lowest temperature at which measurements were made. The coercive field strength rises sharply from approximately 250 volts per cm at 180 K to over 9,000 volts per cm at 4.2 K.

Apparently no systematic investigation of the variation of polarization with temperature in barium titanate ceramics has been previously reported in the literature. When the spontaneous polarization of a ferroelectric is obtained by extrapolation of the linear saturation branch of the loop to zero field strength, the assumption is made that the induced polarization depends linearly on the field strength and is given by $P_s=(\epsilon-1)\ E/4\pi$. It also assumes that the slope of this branch is determined by the magnitude of the initial dielectric constant which is measured with the use of a weak field and high frequency so that reorientation of domain structure does not occur. However, Rzhanov has shown experimentally that this procedure yields accurate results only outside the region of rapid increase of initial dielectric constant with temperature, i.e., outside the neighborhood of the Curie temperature.[10]

The addition of calcium titanate to barium titanate in small percentages results in more uniform electrical properties and greater stability over the important operating range from 0 to 40 C. In general, the magnitudes of the electrical constants are lowered but not excessively lowered.

From saturated hysteresis loop oscillograms of barium titanate ceramic disks, containing 0, 2.5, 5.0, 7.5 and 10.0 percentages of added calcium titanate, has been determined the remanent polarization P_r, the spontaneous polarization P_s, and the coercive force E_c, over the temperature range from 0 to 125 C. Results are presented in Figs. 13, 14, and 15. Data are for single disks only and thus the results are merely representative. The addition of as little as 2.5% calcium titanate shifts the peak in the remanent and spontaneous polarization curves of ceramic barium titanate to much lower temperatures. Higher percentages serve to linearize and lower the curves, but the effect is less marked as the percentage of added calcium titanate is increased. Marked changes in slope occur between 80 and 100 C.

The coercive force E_c is a measure of the energy necessary to reverse the polar axis of the ferroelectric crystal. The dipoles that result in the spontaneous polarization become reversed in direction. In Fig. 15 are plotted values for coercive force versus temperature for the same group of ceramics as those on which the polarization studies were made, the data having been obtained from the same lot of oscillograms. Peaks occur in these curves at approximately 15 C, i.e., in the neighborhood of the transition temperature from tetragonal to orthorhombic. Thereafter with rise in temperature the coercive force falls rapidly and nearly linearly, dE_c/dt being roughly −40 volts per C except for barium titanate alone, where the change is less marked. Small percentages of added calcium titanate markedly raise the coercive force, showing that the stability of the ceramic has been increased.

Graphical Determination of the Fourier Series Coefficients

W. H. MIDDENDORF
MEMBER AIEE

ALMOST all of the many good textbooks on analysis of electric circuits include analysis of nonsinusoidal waves. Equations are usually given which determine the amplitude of each term of the Fourier trigonometric series. If the dependent variable can be expressed in terms of the independent variable, the familiar relations

$$a_0=\frac{1}{2\pi}\int_0^{2\pi} y\,dx \tag{1}$$

$$a_n=\frac{1}{\pi}\int_0^{2\pi} y\cos nx\,dx \tag{2}$$

$$\text{and } b_n=\frac{1}{\pi}\int_0^{2\pi} y\sin nx\,dx \tag{3}$$

may be used to determine the coefficients.[1] In many situations, however, the dependent variable cannot be expressed in terms of the independent variable except by the trigonometric series which the analysis seeks to establish. In that event the relations just given may be changed to permit graphical integration by the method of rectangular approximation. The coefficients are then given by the equations

$$A_0=\frac{1}{m}\sum_1^m y_k \tag{4}$$

$$A_n=\frac{2}{m}\sum_1^m\left[y_k\cos n\left(k-\frac{1}{2}\right)\frac{2\pi}{m}\right] \tag{5}$$

$$B_n=\frac{2}{m}\sum_1^m\left[y_k\sin n\left(k-\frac{1}{2}\right)\frac{2\pi}{m}\right] \tag{6}$$

where

A_0 = constant term of the series
A_n = coefficient of the nth harmonic cosine term
B_n = coefficient of the nth harmonic sine term
y_k = mid-point value of the function in the kth segment
m = total number of segments

Notice that the coefficients are represented by capital letters in equations 4, 5, and 6, to distinguish them from the coefficients obtained with absolute accuracy using the calculus of infinitesimal differences.

This matter of accuracy in the values of the coefficients as determined by equations 4, 5, and 6 should receive some consideration. The summation of the product $y_k \sin n\,(k-{}^1/_2)\,(2\pi/m)$ requires that the values of the function between the limits of the segment do not differ greatly from the value of y_k. Thus, if the wave is irregular, the number of segments m should be increased if fair accuracy is to be obtained. Under such circumstances it is natural for the investigator to select a large number of segments. Even if the curve is a smooth variation and y_k (the mid-point value) is closely equal to all the values of the function over a large segment, the value of m must be selected with care. The second factor of the product shown, $\sin n\,(k-{}^1/_2)\,(2\pi/m)$, must be a close approximation of all the values of the harmonic sine wave that occur in the segment. Thus, if the same accuracy is to be obtained for the coefficients of the higher harmonics, the value of m must be increased over that used for the fundamental and the lower harmonics. It is true that the importance of accuracy usually decreases as the harmonic number increases, since the amplitudes of the waves usually decrease with an increase in n. Nonetheless, a situation can be created wherein each additional sine and cosine wave added to the series makes the resulting composite wave reproduce the original wave less faithfully; i.e., errors of over 100% (per cent) can occur.

The saw-tooth wave shown in Fig. 1 was analyzed by the exact method using equations 1, 2, and 3, and the coefficients compared to those obtained when the approximate equations 4, 5, and 6 are used. Table I shows that the error in B_{10} when 50 segments are used is about equal to the error in B_5 when 25 segments are used, or the error in B_1 when 5 segments are used. Thus Table I indicates that the number of segments must be increased in proportion to the harmonic number, if all coefficients are to be determined with the same order of accuracy. As a general rule, however, this statement is a bit pessimistic. For the usual irregular type of nonsinusoidal wave it is not necessary to increase the number of segments in direct proportion to the harmonic number in order to maintain the same order of accuracy. An increase in the number of segments results in the mid-point value of each segment being more nearly equal to all the other values of the function within the segment. Thus, as the number of segments is increased, the accuracy of the coefficient improves because of the decrease in the deviation of the function from the value of y_k and the decrease in the deviation of the harmonic sine wave from the value of $\sin n\,(k-{}^1/_2)\,(2\pi/m)$. In the case of the saw-tooth wave the mid-point value is the true average for a segment of any width. Thus, the increase in accuracy with an increase in the number of segments shown in Table I is due mainly to an improvement in the value of $\sin n\,(k-{}^1/_2)\,(2\pi/m)$.

Notice also that if only eight segments are used to determine B_5, Table I shows that the error is 117%. Perhaps few investigators would use only eight segments when analyzing a nonsinusoidal wave, but the information given in the preceding paragraph indicates that a similar error would result even using 32 segments, if the coefficients of the 20th harmonic are to be found.

Another method of graphically determining the Fourier series coefficients, the Fischer-Hinnen method,[2] is usually much less laborious than integration by rectangular approximation. This method requires that a point in the harmonic range be determined beyond which all harmonics may be neglected, which may not be easy. Some indication of this point is made possible by determining the d-c component for different higher-order sets of ordinate sums. When the values so obtained are equal, the higher harmonics probably may be neglected.

The need for a method which accurately and quickly determines the coefficients of the higher harmonic terms is made evident by the preceding discussion of the two methods given in most textbooks. A new method is suggested by a study of equations 2 and 3. It is evident from these relations that the coefficient of each term of the Fourier series is equal to twice the average ordinate of the $y \sin nx$ curve; i.e., a curve formed by multiplying the values of the nonsinusoidal function by the values of a unit sine wave having a frequency equal to that of the harmonic.

Any way in which this average ordinate can be found accurately will permit a correct evaluation of the coefficient. One way to find the average ordinate for a period of the nonsinusoidal wave is to determine the average ordinate of each segment and then find the average of these values. This procedure is made practical by selecting a number of segments which is equal to a multiple of the harmonic number of the coefficient sought. If this is done, literal equations can be developed for the average ordinate of each segment. These equations involve numbers determined by the nonsinusoidal function and multipliers whose values are determined by the particular part of the harmonic wave that exists within the segment under study. These multipliers may be developed in the following manner.

If the equation of the straight line segment shown in Fig. 2 is written as

$$y_1=\alpha x_s+\beta$$

where x_s is measured from the left edge of the segment, and the equation of the harmonic sine segment is written as

$$y_s=\sin(x_s+\theta)$$

then the average ordinate of the product of the straight line and the harmonic sine wave for the segment shown bold in Fig. 2 is

$$0_{1s}=\frac{1}{2\pi/m}\int_0^{2\pi/m}(\alpha x_s+\beta)\sin(x_s+\theta)dx_s$$
$$=\frac{m}{2\pi}\left[\alpha\int_0^{2\pi/m}x_s\sin(x_s+\theta)dx_s+\beta\int_0^{2\pi/m}\sin(x_s+\theta)dx_s\right]$$

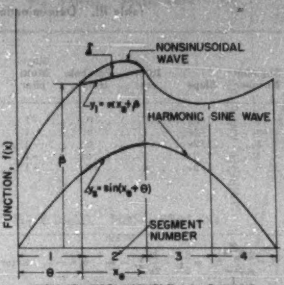

Fig. 2. Typical segments of nonsinusoidal wave and harmonic sine wave

Integrating the first term of the right member by parts yields

$$-\alpha x_s\cos(x_s+\theta)\Big]_0^{2\pi/m}+\alpha\sin(x_s+\theta)\Big]_0^{2\pi/m}$$

The second term of the right member becomes

$$-\beta\cos(x_s+\theta)\Big]_0^{2\pi/m}$$

Thus

$$0_{1s}=\frac{m\alpha}{2\pi}\Big[-x_s\cos(x_s+\theta)+\sin(x_s+\theta)\Big]_0^{2\pi/m}-\frac{m\beta}{2\pi}\Big[\cos(x_s+\theta)\Big]_0^{2\pi/m}=\rho\alpha+\sigma\beta.$$

where

α = slope of the straight line that joins points on the nonsinusoidal wave at the limits of the segment and is related to the scale of the harmonic sought

β = intercept of the straight line at the left hand edge of the segment

ρ = slope-multiplier which depends upon the portion of the harmonic sine term within the segment

σ = intercept-multiplier which is equal to the average of the portion of the harmonic sine wave within the segment

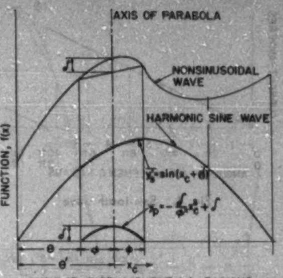

Fig. 3. Parabolic area and harmonic sine wave

The area between the straight line and the function to be analyzed in Fig. 2 is closely represented by the area under a parabola,[3] if the nonsinusoidal function does not have a point of inflection within the limits of the segment. The difference between the area under the nonsinusoidal wave and the trapezoidal area is shown in Fig. 3 for a typical segment. The equation of this parabola may be written as

$$y_p=-\frac{\delta}{\phi^2}x_c^2+\delta$$

if the y-axis is made to coincide with the axis of the parabola. The equation of the sine segment is now written as

$$y_s'=\sin(x_c+\theta')$$

Then the average ordinate of the product of parabola and the harmonic sine wave for the segment shown is

$$0_{ps}=\frac{\delta}{2\phi}\int_{-\phi}^{\phi}\Big[\sin(x_c+\theta')-$$

Table II. Multipliers Which Determine Coefficients of Sine and Cosine Terms

	2	180–360	$\rho_{22}=-1$	$\sigma_{22}=-0.636$	$\tau_{22}=-0.515$
4	1	0–90	$\rho_{14}=1.636$	$\sigma_{14}=0.636$	$\tau_{14}=0.445$
	2	90–180	$\rho_{24}=0.364$	$\sigma_{24}=0.636$	$\tau_{24}=0.445$
	3	180–270	$\rho_{34}=-1.636$	$\sigma_{34}=-0.636$	$\tau_{34}=-0.445$
	4	270–360	$\rho_{44}=-0.364$	$\sigma_{44}=-0.636$	$\tau_{44}=-0.445$
Cosine Terms					
1	1	0–360	$k_{11}=0$	$\lambda_{11}=0$	$\mu_{11}=-0.202$
2	1	0–180	$k_{12}=-0.636$	$\lambda_{12}=0$	$\mu_{12}=0$
	2	180–360	$k_{22}=0.636$	$\lambda_{22}=0$	$\mu_{22}=0$
4	1	0–90	$k_{14}=0.364$	$\lambda_{14}=0.636$	$\mu_{14}=0.445$
	2	90–180	$k_{24}=-1.636$	$\lambda_{24}=-0.636$	$\mu_{24}=-0.445$
	3	180–270	$k_{34}=-0.364$	$\lambda_{34}=-0.636$	$\mu_{34}=-0.445$
	4	270–360	$k_{44}=1.636$	$\lambda_{44}=0.636$	$\mu_{44}=0.445$

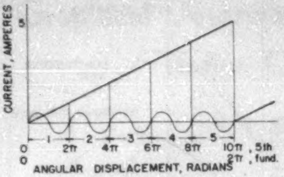

Fig. 4. Saw-tooth wave

$$\frac{1}{\phi^2}x_c^2 \sin (x_c+\theta')\Bigg]dx_c$$

$$=\frac{-\delta}{2\phi}\Bigg[\cos (x_c+\theta')+\frac{2x_c}{\phi^2}\sin (x_c+\theta')-\frac{(x_c^2-2)}{\phi^2}\cos (x_c+\theta')\Bigg]_{-\phi}^{\phi}$$

$$=\tau\delta$$

where δ is defined by Figs. 2 and 3, and τ is the multiplier which depends upon the portion of the harmonic sine wave within the segment.

Likewise, the average ordinate of the product of the straight line and the harmonic cosine wave is

$$0_{1c}=\frac{1}{2\pi/m}\int_0^{2\pi/m}(\alpha x_e+\beta)\cos (x_e+\theta)dx_e$$

$$=\frac{m\alpha}{2\pi}\Bigg[x_e \sin (x_e+\theta)+\cos (x_e+\theta)\Bigg]_0^{2\pi/m}+\frac{m\beta}{2\pi}\Bigg[\sin (x_e+\theta)\Bigg]_0^{2\pi/m}$$

$$=k\alpha+\lambda\beta$$

where

k = slope-multiplier which depends upon the portion of the harmonic cosine term within the segment.

λ = intercept-multiplier which is equal to the average of the portion of the harmonic cosine wave within the segment.

The average ordinate of the product of the parabola and the harmonic cosine wave is

$$0_{pc}=\frac{-\delta}{2\phi}\Bigg[\frac{2x_c}{\phi^2}\cos (x_c+\theta')+\frac{(x_c^2-2)}{\phi^2}\sin (x_c+\theta')-\sin (x_c+\theta')\Bigg]_{-\phi}^{\phi}$$

$$=\mu\delta$$

where μ is the multiplier which depends upon the portion of the harmonic cosine wave within the segment.

The average ordinate of each segment can now be written for the sine and cosine terms as

$$0_s=\rho\alpha+\sigma\beta+\tau\delta$$

and

$$0_c=k\alpha+\lambda\beta+\mu\delta$$

The Fourier coefficients are given in terms of these average ordinates of the segments by the equations

$$A_n=\frac{2}{m}\sum_1^m 0_c \tag{7}$$

and

$$B_n=\frac{2}{m}\sum_1^m 0_s \tag{8}$$

The values of the multipliers have been computed for 1, 2, and 4 segments per cycle of the harmonic sine and cosine waves. Table II presents these values. The method proposed by this paper becomes more attractive when one notices that many of the multipliers are zero when using one or two segments per cycle of the harmonic sought. The multipliers are given two subscripts. The first indicates the segment for which the multiplier is appropriate. The second indicates the total number of segments per cycle of the harmonic.

The method of analysis proposed herein is most easily taught by three examples. The saw-tooth wave previously analyzed by the rectangular summation method will serve as the first example. The coefficient of the fifth harmonic sine term will be determined. Fig. 4 shows the saw-tooth wave of Fig. 1, but the harmonic wave whose coefficient is sought is drawn on the same time axis for ready reference. Of course, this wave cannot be drawn with the correct amplitude. Table III shows the calculations necessary to determine B_5. Notice that the slope is reckoned on the basis of the angular displacement of the harmonic sought. For irregular waves the slope is easily determined by use of a bevel protractor. The tangent of the angle, so measured, times the ratio of the ordinate scale factor, divided by the abscissa scale factor, is equal to the slope.

For the second example, the square wave shown in Fig. 5 will be analyzed to determine the coefficient of the fifth harmonic cosine term. Table IV shows the calculations necessary to determine A_5. Notice that it is possible to use relatively large segments (one per cycle of harmonic) over part of the nonsinusoidal wave and smaller segments where the

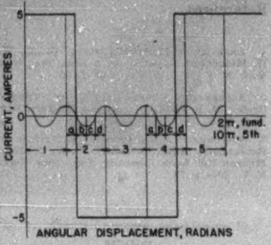

Fig. 5 (left). Square wave

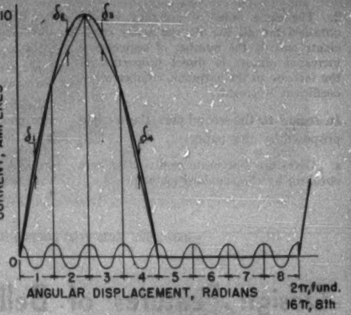

Fig. 6 (right). Half-rectified sine wave

irregularity of the wave demands. When a segment is broken into smaller parts, the average of the ordinates of the parts is equal to the average ordinate of the segment.

The last example will be the analysis of the half-rectified sine wave shown in Fig. 6. The coefficient of the eighth harmonic cosine term will be determined. The necessary calculations are shown in Table V. Notice that for nonsinusoidal waves without discontinuities the sum of the slopes will equal zero. Thus, if one segment per cycle of the harmonic sought is used, the sum of the slopes times the multipliers will equal zero for both sine and cosine coefficients.

These three examples show the basic calculations necessary to analyze a wave by this method. Just as with these examples, most nonsinusoidal waves will not require that all three types of calculations be made. In that event it is not necessary to include the columns of zeros as was done here. Since the occurrence of zeros is the rule rather than the exception, the investigator will do well to determine how many calculations can be avoided before the analysis begins.

Besides its use in determining the coefficients this method permits generalizations to be made concerning the harmonic content of nonsinusoidal waves. This can be of advantage in determining the point in the harmonic range beyond which all harmonics may be neglected. Most important of these generalizations are:

1. A wave that can be faithfully represented by one segment per cycle of the harmonic sought will not yield a coefficient for the sine term of that harmonic unless the wave contains at least one finite jump.

2. A wave that can be faithfully represented by one segment per cycle of the harmonic sought will yield a coefficient for the cosine term of that harmonic proportional to the algebraic sum of the parabola heights divided by the number of segments.

It is true that the waves analyzed in this paper do not require the use of graphical methods. These nonsinusoidal waves were chosen for graphical analysis because the coefficients so obtained can be compared to those known from exact analysis. The exact value of the coefficient is given in the appropriate table (see the coefficient represented by the lower case letter) as well as the error in the value determined the method of this paper. The maximum error of 3% is well within the error to be expected when values are read from a graph.

Although this method of analysis is valid and accurate for the determination of the coefficients of the lower order harmonics, these situations usually require that so many segments be used for each cycle of the harmonic that the computations become excessive. For any nonsinusoidal wave the number of segments chosen must be large enough that the function does not have points of inflection within the segments. The author has used this method for problems with as many as eight segments per cycle of the harmonic sought (the second). The error of the result was less than 3%. However, similar accuracy was obtained by the method of rectangular approximation with a comparable amount of work using 36 segments. The Fischer-Hinnen method also gave comparable accuracy with much less effort. It therefore seems reasonable to propose that the method presented in this paper be used to determine the coefficients of the higher order harmonics and the Fischer-Hinnen method be used for the coefficients of the lower order harmonics.

Conclusions

This paper has given the results of a study of the Fourier series coefficients. The study was twofold. It has been concerned with:

1. The accuracy of the coefficients when found by the standard method of graphical analysis and,

2. A new method of determining the coefficients.

In regard to the first part, it has been found that:

1. Errors of over 100% can result when using the standard method of graphical analysis.

Table V. Determination of A_8 for Half-Rectified Sine Wave

Segment Number	Slope	Intercept	Parabola Height	Slope-Multiplier	Intercept-Multiplier	Parabola-Multiplier	Slope × Multiplier	Intercept × Multiplier	Parabola Height × Multiplier
1	1.12	0	0.35	0	0	−0.202	0	0	−0.071
2	0.47	7.07	0.68	0	0	−0.202	0	0	−0.137
3	−0.47	10.00	0.68	0	0	−0.202	0	0	−0.137
4	−1.12	7.07	0.35	0	0	−0.202	0	0	−0.071

6	0	0	0	0	0	−0.202	0	0	0
7	0	0	0	0	0	−0.202	0	0	0
8	0	0	0	0	0	−0.202	0	0	0
							$\sum_{1}^{8} 0_c = 0$	+ 0	−0.416

$$A_8 = \frac{2}{m}\sum_{1}^{m} 0_c, = \frac{2}{8}(-0.416), = -0.104; \quad a_8 = -0.101. \quad \text{Error} = 3\%.$$

2. The same order of accuracy will be obtained for all the Fourier series coefficients only if the number of segments is increased almost in direct proportion to the increase in the harmonic number whose coefficient is sought.

In regard to the second part, the method proposed by this paper:

a. Gives more accurate results than were obtained by the standard method.

b. Requires fewer calculations for the three nonsinusoidal waves analyzed.

c. Suggests generalizations that permit rapid estimations of the amplitudes of the harmonics.

It must be remembered, however, that this method loses many of its advantages when more than two segments per cycle of the harmonic sought are used to fit the straight lines and parabolas to the irregular variations of the nonsinusoidal wave.

Design Features of Bell System Wire Spring Relays

H. M. KNAPP
NONMEMBER AIEE

THE Bell Telephone System wire spring relays have become the basic circuit components of telephone switching systems developed during the past few years. These relays are provided in many varieties to meet circuit needs. They are similar in operation and construction and have been described to a large extent in earlier publications.[1,2] It is the purpose of this paper to highlight some of the design features which permit automatic control, during manufacture, of important operating characteristics. This subject has not been covered in the earlier articles and is of considerable importance to low-cost manufacture and proper operation of these relays.

While control during manufacture of some of the operating characteristics is also true of other relays, the aim in the development of wire spring relays was to attain essentially all desired characteristics automatically without hand adjustment. This provides a more uniform product at low cost but calls for special design and manufacturing features. Before the discussion of these features, a brief description of the three classes or families of wire spring relays is in order.

The General-Purpose Relays

The general-purpose family of relays has now grown to more than 200 codes even though it is the continuing objective to keep the codes to a minimum. However, this number is justified economically because of the variety of switching requirements encountered. These requirements call for contact combinations ranging between 1 and 24 contacts per relay, high-speed operation in some cases, slow operation in other cases, and applications requiring high sensitivity, marginal operation or unusually long life—up to a billion operations.

This variety of operating conditions is accomplished with relays having basic parts which are similar and, in some cases, do not require additional tools and machines. For example, Fig. 1 shows a relay with 12 make and 6 break contacts. The light armature, which is designed for speed, limits the number of contacts which can be operated to a maximum of 18. For added pull, a heavier armature is employed and is shown on a relay equipped with 24 make contacts in Fig. 2. Fig. 3 illustrates a relay with relatively few contacts and a buffer spring. This spring is used to control the release current of relays where special release requirements must be met. These three cases illustrate that, by minor differences in some parts or by using simple additional parts, a wide variety of operating conditions can be met. Hence the term general purpose is applied to this class of relays.

The Multicontact Wire Spring Relays

The multicontact relays are similar in construction in most respects to the general-purpose relays. They are larger because they operate more contacts and must meet equipment requirements as to spacing of terminals and multiple strapping of wires between relays. They perform the special function in telephone switching of connecting a large group of leads from one switching frame to another. In new systems they are used in units of 30 contacts. One of these is shown in Fig. 4. They are faster in operation than the former flat spring multicontact relays and they have much longer life. They are also designed as an electrical and mechanical replacement for the former relays. For these applications, two 30-contact units are mounted on a common frame. One of these relays is shown in Fig. 5.

The Dual Relays

The dual relays are the third family of wire spring relays. They are a recent extension of the wire spring relay principles.

Each dual relay consists of two independent relays mounted on the same structure; see Fig. 6. They are designed to make more efficient use of space and materials where no more than five transfer contact combinations are required for each relay. They employ the same wire blocks, and one dual unit occupies the same mounting space as a single general-purpose relay. The greater economy of the dual relay within its field is made obvious by Fig. 7 which shows the parts needed to do the same job with both types of relays.

Automatic Control of Operating Characteristics—Spring Forces

Most of the important operating characteristics in all of these relays such as speed of operation, contact reliability,

etc., relate directly to forces developed by cantilever springs, to armature travel and to the contact closure points during the armature stroke. Allowances must be made in establishing their magnitude, for variations in manufacture and for changes as a result of aging and use. The discussion which follows will be limited essentially to design features which permit automatic control of forces, travel, and contact closure without resorting to hand adjustment in manufacture.

Of these three, the spring forces are the easiest to obtain automatically. These are attained by machine-bending of the springs prior to assembly in the relay. When assembled, the proper tension is obtained by reason of the deflection caused by this bend. The stiffness of the spring should be low so that the amount of deflection can be as large as safe stresses and other considerations permit in order that manufacturing variations in offset, spring thickness, etc., will have little effect on the desired force. Several examples are cited to illustrate this principle as applied to the design of wire spring general-purpose relays. The other types of wire relays employ similar features.

CONTACT FORCE

The magnitude of the contact force contributes to contact reliability of the relay and to the reduction of contact chatter. The lower the force the greater is the likelihood of failure caused by dust, and of chatter or momentary contact openings caused by spring vibration. While high contact force contributes to better contact performance, more power is needed to operate the relay. Hence good control in manufacture of an optimum value of contact force is important.

Contact force for both make and break contacts is governed almost entirely by the large bend formed in the movable wires during manufacture. The movable wires and the effect of this bend before and after assembly of the wire block into the relay are illustrated in Fig. 8. The force developed by the wire is applied against the actuating card when the contact pair is open and against the stationary contact when the contact pair is closed. Hence, this deflection provides the contact force. With the use of low-stiffness wire, which permits a large deflection, the normal manufacturing variations in the amount of bend, in wire diameter, etc., and variations resulting from wear in service have only a minor effect on the total force developed. Hence, a well-controlled contact force is assured not only in manufacture but also during the service life of the relay.

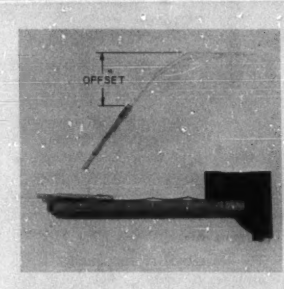

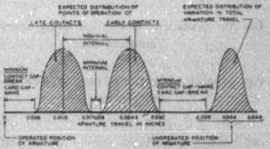

Fig. 12. Components of armature travel on a relay with sequence contacts

Note: No hand adjustment for: contact interval, individual contact closure, and armature travel

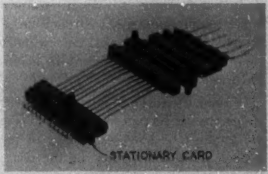

Fig. 13. Stationary wire block assembly

ARMATURE HEEL FORCE

The armature heel force is that of the armature legs against the core at the pivot point. This force should never reach zero during the life of the relay and should be substantially higher to minimize the bounce of the armature against its backstop on release which could cause reoperation of the contacts. The large predeflection of the armature hinge spring governing this force is illustrated in Fig. 9.

BALANCING SPRING FORCE

This is the force, also obtained by machine-bending before assembly, exerted by the balancing spring against the actuating card. It holds the make contacts open and the armature against its backstop with the relay unoperated. It guarantees the release of the relay and supports the card. Its application is illustrated in Fig. 10.

STATIONARY WIRE BLOCK TENSION

The front block of the stationary wires exerts a force against each core plate arm by reason of the machine-made pretension bend in the wires. This is illustrated in Fig. 11. The control of this force is important because its magnitude determines whether the block is held firmly in position against vibration so that wear between the block and the core plate does not occur. Wear at these surfaces could cause objectionable changes in operating characteristics.

Despite the importance of all of these forces in the proper functioning of the relay, their attainment, automatically, by large predeflections made it unnecessary in most cases to specify direct requirements, to hand-adjust, or even to inspect. This results in a more uniform product at lower cost. The only exception applies to the balancing spring which requires some adjustment on relays where the range of variation must be reduced to meet close current flow or armature back tension requirements.

Short Armature Travel

The importance of making armature travel as short as possible, consistent with proper operation of the relay, is obvious to anyone familiar with relay design. Smaller armature movement results in shorter operating and releasing times, greater operating sensitivity, longer life, and less chatter of the contacts.

To avoid the hazards inherent in short travel, the factors governing this must be controlled as closely as possible. The factors to be discussed herein are the distribution of the points of operation of the contacts, the interval of sequence

contacts, and the distribution of total travel itself, as shown in Fig. 12. Close control of these characteristics in manufacture means narrower distributions and, hence, shorter travel is permitted without upsetting design margins for wear, atmospheric changes, etc.

To obtain close control in these cases, the design objective was to keep the number of variables and dimensions governing these characteristics to a minimum. It was also recognized that the design should lend itself to the type of manufacturing operations in which close control of the essential dimensions would be possible. For example, a rolling or a swaging operation provides closer control of a dimension than one governed by a forming operation.

Distribution of Contact Closure Point

The closure point of the contacts in the stroke of the armature is most difficult to control automatically within limits comparable to those obtained usually by hand adjustment. This is because of the number of dimensions that would normally affect this characteristic. Also the large number of contacts which these relays are designed to operate complicates this problem. However, the fact that one contact of each pair is stationary facilitates the use of design and manufacturing techniques to reduce the number of variables. It permits the stationary card, usually referred to as the front molded block, to be an integral part of the stationary wire assembly, as shown in Fig. 13. This led to a new manufacturing technique which positions the contacts in welding where they need to be in the assembled relay.

The location of these contact surfaces is an important dimension controlling the contact closure point. The several primary dimensions governing this characteristic, including the location of the stationary contacts, dimension *B*, are illustrated in Fig. 14. If the stationary contacts were attached to the wires by the usual welding methods, their location would be affected by additional factors. The effect of these factors are shown in Fig. 15(A) and are caused by:

1. Variations of wire position in the block.
2. Warpage of the block in molding.
3. Deflection of the block caused by the tension of the wires holding it down.
4. Deflection of the wires caused by the pressure of the welding electrode.

Fig. 18. Major dimensions controlling armature travel on general-purpose relays

These variables are eliminated by locating the contacts in the process of welding, relative to the front mounting surfaces of the stationary wire assembly, with the use of a special welding process. This is done while applying the same forces on the part in the welding fixture as are applied in the assembled relay. Fig. 15(B) illustrates the good alignment of the contact surfaces obtained by this method.

To accomplish this result, a special welding process was developed by the Western Electric Company.[9] This process, which is a special form of percussive or arc welding, permits one welding electrode to be connected to the terminal end of the wire, well away from the weld zone. The other electrode is in the form of a movable jaw which holds the contact being welded in a fixed plane relative to the front mounting surfaces of the stationary wire assembly. This is shown schematically in Fig. 16. With the usual welding, both electrodes must be connected adjacent to the weld zone, which results in deflection of the wire ends and poor control in the location of the contact surfaces.

Even with the elimination of variables as just described, the margin in the automatic control of contact closure did not appear adequate since it might not always be possible to meet all the desired limits on the controlling dimensions. Because of this, a means for making a gang adjustment was provided in the relay. The front-molded block is supported on the two adjustable arms of the core place; see Fig. 11. These arms can be bent with the use of a screwdriver inserted in the slot so as to alter the position of the fixed contacts as a group. By this means, manufacturing variations common to all the contacts, such as the variations of dimensions *C* and *E* of Fig. 14, can be removed. Hence, such variations were excluded in the analytical determination of range of contact closure which, in turn, permitted shorter armature travel. No provision is needed for adjusting individual contacts because of special design and manufacturing features such as just described. The reduced adjusting effort results in lower manufacturing cost.

Contact Interval

The interval of a sequence combination, such as a break before make, is governed only by the four dimensions shown in Fig. 17. Dimension A, the card dimension controlling the separation of the movable wires, is obtained by punching and shaving operations. Dimension B, the height of the stationary contact, is controlled largely by a rolling operation in the manufacture of the contact tape. This contact is sheared from tape consisting of a layer of palladium on top and another layer on the bottom of a nickel base. Dimensions C_m and C_b, the height of the offset and the contacts of the movable wires, depend upon the accuracy of a swaging or coining operation. In this latter case, it would have been better to have used straight instead of offset wires for the sake of simplicity and control. However, space and assembly considerations as related to the actuating card prevented this.

Control of Armature Travel

The variation in total travel is one of the factors determining the amount of travel needed. As travel becomes smaller because of manufacturing variations, contact separation of a make contact, for example, may be seriously reduced.

The travel on wire spring relays is not adjustable. Like most of the other characteristics, it is tool-controlled. The two dimensions shown in Fig. 18 determine the travel on general-purpose relays. These are the height of the backstop tab above the core, dimension A, and the thickness of the armature including the nonmagnetic stop disks, dimension B. For improved control, the tab is shaved after forming, and the portion of the armature engaging the backstop is swaged to a reduced but more uniform thickness.

Summary

Special design features of the Bell Telephone System wire spring relays which contribute to automatic control, during manufacture, of important operating characteristics have been described in this paper. These characteristics relate directly to spring forces on which automatic control can generally be accomplished, and to armature travel or components of travel which are more difficult to control automatically. To attain the desired end, characteristics such as speed, life, sensitivity, etc., calls for close control of important dimensions relating to travel. While closer limits could be met in certain cases by expensive hand adjustments, thereby accomplishing still further reduction in armature travel, it is believed that the best economic balance has been achieved in these relays between manufacturing cost and value of additional speed, life, and other benefits resulting from further decreases in travel.

The Full Stature of the Crossbar Tandem Switching System

J. MESZAR
MEMBER AIEE

CROSSBAR tandem is a relatively young switching system. It first went into service in 1941. Its original role was well defined although, in retrospect, severely limited; it was to take over in large metropolitan areas the functions of the panel-type office selector tandem system, even as the no. 1 crossbar system[1] took over from the local panel central office. However, even at that early date, its latent potentialities for a broader field of usefulness were appreciated. This appreciation could not then be implemented because during World War II development of telephone switching facilities at Bell Telephone Laboratories came to a near standstill. The needs of national defense transformed switching development engineers almost overnight into designers and teachers of radar, sonar, etc. True, there followed the great postwar surge of switching development activities but these, in turn, involved new systems urgently needed to start customer and operator nation-wide dialing.[1] This period saw the development of the no. 5 crossbar local switching system,[2] the automatic message accounting (AMA) system,[3] and the *4A* crossbar long-distance switching system.[4] In view of this tremendous development program of new systems, the available development talent had to be practically rationed, and so only a moderate amount of effort could be applied to the crossbar tandem system to increase its scope of usefulness. The outcome of this effort and the basic description of the crossbar tandem system were presented in 1950.[5] The closing paragraph of this 1950 paper was the following statement: "An extensive development program is now in progress to incorporate new features which will still further enhance the usefulness of crossbar tandem in the rapid expansion of automatic switching in the Bell Telephone System." By now, this extensive development program referred to is nearing completion, and it is the purpose of the present paper to highlight the significant new features embodied in the 1956 design version of the crossbar tandem system.

It is well to bring out that these new features have not been achieved by any great technological changes in the crossbar tandem system. The 1956 design version of the system remains a typical electromagnetic switching system based on crossbar switches and relays, as was the 1941 version. Here and there, of course, entirely new devices and circuit configurations have been incorporated,

in accordance with the over-all progress of electromechanical switching technology. Examples of such innovations are the use of wire spring relays for general control functions, sealed contact relays as memory elements, cold cathode gas tubes as pulse-responsive devices, etc. However, the impressive results of the crossbar tandem developments reported herein are not in this direction. The true impact of these recent developments lies in the great increase in the functional versatility and level of responsibility possessed by the 1956 design version of crossbar tandem as compared to its earlier version.

Local Tandem Functions

As was mentioned, the original mission of crossbar tandem was to take over the functions of the local panel office selector tandem system. In accordance with the pattern of Fig. 1, the basic need for a local tandem switching system arises in large metropolitan areas where local telephone service is furnished by dozens or even hundreds of central offices. In such areas tandem systems are used:

1. To effect trunking economies by combining small amounts of interoffice traffic originating in the various central offices and routing this combined traffic over a common trunk group to the required destination, thus eliminating the necessity for inefficient, small, direct interoffice trunk groups.

2. To effect central office economies by serving as a machine language interpreter between the different types of central offices, thereby eliminating the costly necessity of equipping every central office for direct communication with every other type of central office.

3. To effect over-all service economies by centralizing equipment for rendering 1-way message service (weather reports, etc.) and equipment needed as normal adjuncts of telephone service (charging equipment, etc.). Centralization results in efficient use of such equipment as compared with furnishing the same at each local central office requiring it.

TANDEM TRUNK SWITCHING

The basic structure of the crossbar tandem system was devised to fulfill eminently these fundamental objectives of a local tandem switching system. Fig. 2 is an over-all functional block diagram of the crossbar tandem system.

As indicated on this figure, the switching network of the system consists of the by now well-known crossbar link frames. Incoming trunks from the calling central offices appear on trunk link frames and outgoing trunks to the called central offices appear on office link frames. Through a system of links and junctors, which interconnect the crossbar switches on these frames, any incoming trunk can be connected to any outgoing trunk. For each connection there are several possible paths (or channels) through these frames and, on a call, one of these paths is selected by the common control equipment.

To establish a path, the incoming trunk calls for the services of the common control equipment. This equipment consists of a small number of elements (senders, markers, etc.), each of which is called into service for a relatively short time, performs its functions, releases, and is free to serve another call. The basic functions of these common control elements are:

1. Store the digits as they are received (sender function).

2. Translate these digits into switching control information (marker function).

3. Test for and select an idle outgoing trunk (marker function).

4. Test for and select a matching set of

connecting links between the incoming trunk and the outgoing trunk (marker function).

5. Outpulse as required (sender function).

Over the years, this original switching plan of the crossbar tandem has proved to be highly satisfactory for meeting the first fundamental tandem system objective of enabling trunking economies to be effected in large metropolitan areas. Its switching speed, traffic capacity, and trunking flexibility are all adequate, since its control circuits are fast, and it can accommodate a maximum of about 3,000 incoming trunks and 4,000 outgoing trunks assignable in a wide range of group sizes.

Machine Language Interpreting

The second fundamental tandem system objective of effecting central office economies by functioning as a machine language interpreter focuses attention on the common control elements of the system, in particular, the sender. The sender should really be called the register-sender because it has the dual function of registering initially the called telephone number and, subsequently, after the marker has established the connection through the office, of sending information forward to the succeeding office.

The senders are the natural units of the tandem system for acting as machine language interpreters. Senders can be readily designed to receive digits in the language of the calling central office, and to send forward digits in a different language as required by the called central office.

One of the measures, then, of the full stature acquired by the cross-bar tandem system is the versatility of its senders. The preceding system, i.e., the panel sender tandem system, could only receive digits in one machine language called the panel call indicator (PCI). In this language, the tandem office receives from the originating central office a set of timed code pulses comprising different magnitudes and polarities of direct current. The 1956 design version of crossbar tandem has this same ability of receiving PCI pulses, but it also has a greatly increased competence along these lines. It has the ability to receive digits from calling central offices in three additional machine languages:

1. In the dial pulsing (DP) language, in which digits come to the tandem in terms of simple decimal ON-OFF pulses of direct current.

2. In the multifrequency (MF) language, in which the digits come to the tandem in

terms of pulses comprising pairs of five voice frequencies.

3. In the revertive pulsing (RP) language, in which the tandem office pulses its selection progress back to the calling central office with d-c ON-OFF conditions until the called number is matched in the central office.

These four varieties of machine language represent the inpulsing capabilities of the 1956 crossbar tandem system. On the outpulsing side, the system also has full versatility. Its new senders of the PCI, DP, and MF varieties can forward-pulse in any of the aforementioned four machine languages. Need has not arisen thus far, and is not likely to arise, for equipping the RP senders with MF outpulsing. In fact, all the senders can even use a fifth machine language in the forward direction. This is the language of "meaningful silence." It is used, for example, when the tandem office establishes a connection to certain switchboard operators ahead on the straightforward (SFD) basis. In this case, the forward operator receives a request for her action verbally from the originating point through the tandem office.

In view of these machine language capabilities of the crossbar tandem system, it can now be used for interconnections between all the central offices situated within dial cities, between these offices and those in surrounding exchanges, and between different offices in the surrounding area. Fig. 3 portrays these capabilities.

This figure is a block diagram of sources and destinations of telephone traffic that can be routed through the crossbar tandem system. It also shows the types of machine language that may be received from these sources or sent to the destinations. Incidentally, this figure already indicates that the crossbar tandem has outgrown its original mission of interconnecting only local central offices. It may now be also used to set up connections to and from and between long-distance switching systems. More will be said about this later.

EQUIPMENT CENTRALIZATION

As was previously stated, the third fundamental objective of a local tandem system is to effect over-all service economies by centralizing equipment for 1-way message services, and for equipment needed as normal adjuncts of telephone service. In the first category are such existing popular services as up-to-the-minute local weather reports, time-of-day announcements, etc. The centralization of this type of service in the crossbar tandem system required no significant extension of its features; for these purposes, the tandem's function is the normal one of connecting the calling customer to a destination, which is a simulated operator-type central office generally furnishing recorded announcements.

Centralization of equipment needed as normal adjuncts of telephone service is exemplified by the centralization of charging facilities. Simple charging facilities for 1-unit scoring of a customer's message register are, of course, part of dial central offices. However, control arrangements for zone-message charging in panel-type central offices have been incorporated in the crossbar tandem system right from the start. Zone-message charging involves the operation of the customer's message register one or more times on a single call, depending on the distance involved and the length of the conversation. Although the panel central office circuits could be arranged for this feature, it was more economically accomplished by incorporating the charge-calculating arrangement in the crossbar tandem and operating the customer's message register by signals passed over the trunk to the originating central office.

Zone-message registration did not require separate functional control units in the crossbar tandem. It is accomplished as one of the useful by-products of common control system design. From the called central office code, the marker can readily determine the terminating rate zone. Incoming trunks, in turn, can be grouped into originating rate zones, and this information is also available to the marker. Thus, the marker can readily select the appropriate one of the originating-terminating rate-zone combinations and set the incoming trunk for the corresponding charge rate.

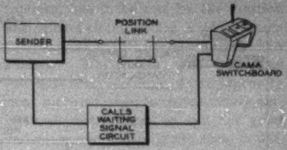

Fig. 7. Association of calls-waiting signal circuit

Obviously, zone registration is satisfactory only for bulk-billed message charging. A far more flexible telephone message billing scheme is the AMA system.[5] In this system the necessary charging information for both bulk-billed and detailed-billed messages is automatically recorded at the central office on paper tape. The record is then processed at the accounting center through a series of information-processing machines.

The introduction of this AMA system was indeed a major step in expanding dial-telephone service with its inherent speed, convenience, accuracy, and uniformity. With AMA recording in a central office, from the standpoint of billing, all restrictions were removed from customer direct-distance dialing (DDD). However, this AMA recording equipment is relatively expensive. In general, its use can be justified economically only in new central offices of the no. 5 and no. 1 crossbar type into which it has been fully integrated. The grafting of this type of automatic recording equipment on thousands of central offices of older design (step-by-step and panel-type) as well as on the many existing No. 1 crossbar offices would be too costly. But the cutomers of these central offices should not be denied the unquestioned advantages of DDD. In this situation, the principle of centralization is applied. By putting the recording equipment at a central point to serve the customers of many central offices, its cost per central office becomes acceptable. Therefore, centralized automatic message accounting (CAMA) has been added to crossbar tandem.[6] With this scheme, if a customer dials a call that requires automatic recording of billing data, the call is routed by the local central office to the crossbar tandem office for such recording.

Unlike zone registration, CAMA required the integration of several major new common control circuits into crossbar tandem. This is shown by Fig. 4.

Fig. 4 is a functional block diagram of

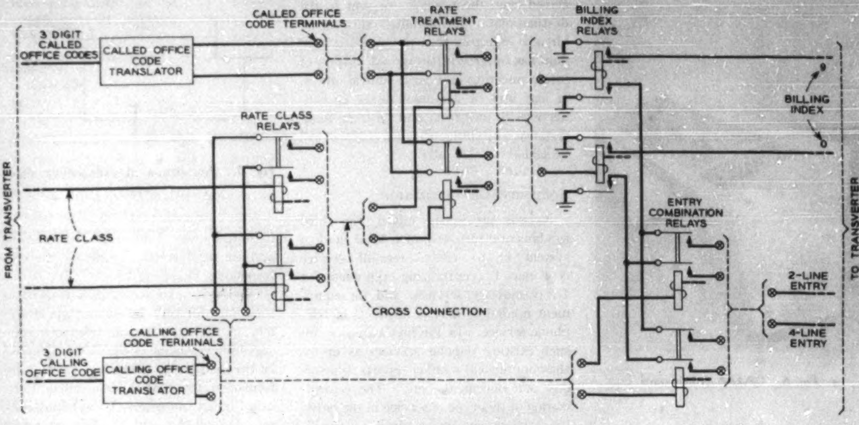

Fig. 8. Simplified schematic of billing indexer

the crossbar tandem system with the first version of CAMA. In this arrangement the sender and marker, of course, retain their previous call-completing functions. However, the sender now has additional major assignments. It must register not only what number is being called but also who will pay for the call, i.e., the calling telephone number. Developments will be completed in the near future to enable the central offices which are working into crossbar tandem CAMA to identify automatically the calling number and pulse this information into the tandem sender over the trunk. At present, to get this information, the tandem sender has to call for the momentary assistance of an idle one of a group of operators. This operator asks the calling customer for his telephone number and, by numerical push buttons, inserts this information into the sender. The sender then passes both the calling and called telephone numbers to the transverter which translates and converts these numbers into the AMA digit-and-word-code structure for subsequent recording. The transverter also requests the billing indexer to determine the applicable charging plan based on the calling and called points and to decide whether the AMA record should or should not include details such as are needed for the customer's toll service statement. Then, under the direct control of the transverter, the recorder perforates into the AMA tape the initial information on the call, including the number of the incoming tandem trunk involved. This last piece of information is furnished by the call-identity indexer. All these CAMA common control elements, including the CAMA operator, finish their respective tasks within a fraction of a second to a few seconds, and are then immediately available for the next call. Meanwhile, the marker has, of course, established the connection, and the sender now completes pulsing forward to the succeeding office. When the called customer answers, the crossbar tandem incoming trunk through the call-identity indexer requests the recorder to punch into the tape the trunk number, and the time of answer, as furnished by the master timer. This same operation is repeated when the customers finish their conversation. These three separately recorded pieces of information on one call are identified by the common trunk number. The CAMA record is processed at the accounting center with the same machines as an AMA record from a local central office.

The significance of this crossbar tandem CAMA scheme can be readily seen. With one stroke, the service advantages of wide-range dialing could now be offered to millions of telephone customers. The first version of this scheme was naturally developed to benefit the greatest number of customers in the large metropolitan areas served mainly by panel and no. 1 crossbar central offices. To expedite early introduction, this initial version was devised so that it requires practically no changes in the central offices it serves. Most of these central offices have had all along the ability (or could acquire it by minor modifications) to make the simple decision whether a call is or is not an extra charge call and, if it is, to transmit it by PCI pulsing to the crossbar tandem office. However, these same central offices have a capacity for 7-digit calls only, and so the initial version of the crossbar tandem CAMA was also a 7-digit PCI system. Even with this limitation, it provided a striking extension of customer dialing. For example, the first installation of crossbar tandem CAMA enabled the customers of 85 central offices in Washington, D.C., and in suburban Virginia as well as Maryland to dial each other directly and to dial their own calls to Baltimore and to other nearby toll points. The second installation enabled 800,000 telephones in 99 Detroit panel and no. 1 crossbar central offices to dial each other directly, and to dial to 63 other communities in Michigan and nearby Canada. The map of Fig. 5 shows this dialing area.

Other large installations of this original 7-digit PCI version of crossbar tandem CAMA are now in service. Some of these subsequent installations, such as the one in New York, opened up a second 7-digit area (New Jersey) for customers to dial into by using the special directing-code of "1-1" for which most of the panel and no. 1 crossbar offices could be readily equipped. This special directing code simply serves to set the central office for transmitting the called number to the crossbar tandem serving the second area

After the introduction of the 7-digit PCI version, development effort has, of course, continued and crossbar tandem now has senders for handling CAMA calls

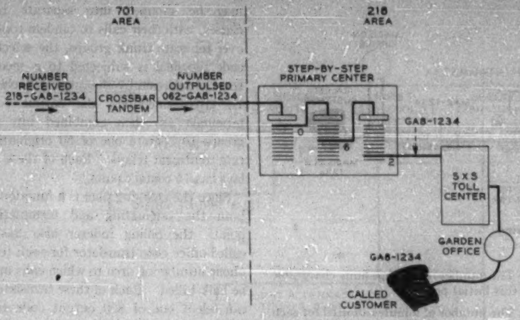

Fig. 9. Code conversion

in the DP as well as in the MF languages; there exists no need for a RP CAMA sender. These latest senders also have a 10-digit-call storage capacity. Thus, the 1956 version of crossbar tandem is designed to handle and record billing data for DDD calls of nationwide scope from central offices that can transmit to it such calls in either the MF or DP language. The former is in anticipation of newly developed storage and outpulsing capabilities that will soon be incorporated into panel and no. 1 crossbar central offices. The latter, in turn, is to extend DDD service to customers served by step-by-step type of central offices, who may dial a simple directing code (such as 1-1-2) to reach the crossbar tandem office and follow, without interruption, with the full called number.

THE CAMA OPERATOR

The transverter, recorder, master timer, and call-identity indexer of the crossbar tandem CAMA system have much in common with the corresponding units of the central office or local AMA (LAMA) system. Hence, they will not be elaborated on in this paper. The two entirely new control elements are the CAMA operator and the CAMA billing indexer. Both of these deserve some remarks.

The over-all function of the CAMA operator has already been stated. In effect, she is a translator, converting the spoken words of the calling customer into digital machine signals acceptable to the CAMA sender, a function which cannot as yet be accomplished economically by electric circuitry. The technical significance of this method of translation is that it poses the problem of integrating a human being with the team of common control units of an otherwise fully automatic system. Such integration, of course, brings its own special requirements.

The first one of these special requirements is that, in contrast to the indifference of the automatic units, a human being needs convenient and pleasant working space. The low, modern, streamlined, sheet-metal, cordless CAMA switchboard of Fig. 6 was designed with this in mind. It provides a convenient work key shelf, and its pleasant color treatment makes a major contribution to a cheerful operating room.

The second special requirement brought about by the integration of operators with the CAMA control circuits is that these control circuits must insure uniform demand for the services of each operator of a working group. An automatic unit does not object to being first choice and thereby to be called upon to carry a heavier work load than a last-choice circuit. In contrast, an operator would. This requirement of highly uniform load distribution has to be met by the position link control circuit of Fig. 4 which hunts for and assigns idle operators to CAMA senders. While this unit comprises standard relay circuitry, much ingenuity went into its design to insure nearly perfect call distribution, in spite of great variations in operator group sizes, in patterns of occupied positions, and sharp fluctuations in incoming CAMA traffic.

Still another aspect of the integration of operators with CAMA comes about because the physical equipment of the crossbar tandem system can be and is often installed in buildings in which there may be no operators' quarters with rest room, etc., facilities. In fact, the location of the building itself may not be the most advantageous from the standpoint of staffing it with operators. Here again, senders, markers, and their likes are not choosy as to location, while operators can be. So, the 1956 version of crossbar tandem offers within-building or remote CAMA switchboard operation; the designed signalling range for remote operation is a maximum of about 30 miles.

These measures are, of course, in the nature of concessions to the human translators. There are, however, factors on the other side of the ledger in connection with this problem of using operators as full partners of automatic control circuits. Control circuits have the same fixed, uniform work time under all conditions; they do not hustle more when the load piles up. In contrast, good operators will increase the tempo of their performance if they receive indication that this is necessary to catch up. For this reason, the crossbar tandem CAMA system includes a calls-waiting signal circuit. Fig. 7 shows how this circuit fits into the system.

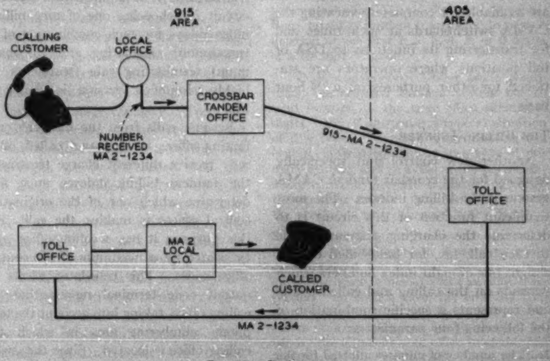

Fig. 10. Prefixing

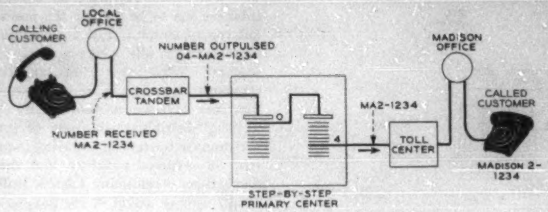

Fig. 11. Prefixing

The lamp standard prominent in Fig. 6 is furnished once in each division of ten switchboard positions and contains three calls-waiting lamps colored green, white, and red. These lamps are controlled by the calls-waiting signal circuit which automatically correlates the number of occupied positions with the number of senders waiting for operators. It can thus indicate the unserved load per occupied position, with increasing load signified by the lighting of the green, white, and red lamps in that order. A multiple of the white lamp also appears on the key shelf of each position. By means of these positional white lamps, the operators know when it is time to put in the extra effort. The colored lamps on the division standard, in turn, enable the supervising operator to regulate the operating team size to match the traffic load conditions.

Another advantage is the flexibility of the human being for doing various tasks in contrast to the highly specialized common control robots. These are used during night hours when CAMA traffic in the crossbar tandem reduces to a negligible level. At such times the robots continue their normal specialized tasks for the occasional call. In contrast, arrangements are available for completely vacating the CAMA switchboards at such times and for transferring its functions to DSA or toll positions where operators are stationed for other purposes on a 24-hour basis.

THE BILLING INDEXER

Another new control unit specifically designed for the crossbar tandem CAMA system is the billing indexer. The most significant function of this circuit is to determine the charging plan applicable to each call, i.e., for bulk-billed calls it assigns one of eight index numbers which depends on the calling and called points and represents a specific combination of the following four parameters:

1. The number of minutes allotted for the initial conversation period.
2. The number of message units chargeable for this initial period.
3. The number of minutes allotted for each overtime conversation period.
4. The number of message units chargeable for each overtime period.

For detail-billed calls, the billing indexer assigns a single index number irrespective of origin and designation. A separate billing index is also assigned to nonchargeable test calls.

As was mentioned previously, the second significant function of the billing indexer is to determine whether the CAMA record should or should not include details such as are needed for the customer's toll service statement. In local AMA offices, the message billing index is relatively easy to obtain as it is practically a function of the terminating office only. In crossbar tandem, however, the complexity of obtaining this index is multiplied by the large number of originating central offices, which may also be in different telephone numbering areas, and, of course, by the extensive bulk-billed tandem terminating coverage.

While the billing indexer is an intricate circuit, in principle it is straightforward. Technically, it is a multistage selecting circuit for choosing one of nine billing-index relays for each combination of 50 (maximum) originating and 75 (maximum) terminating rate treatments. A highly simplified version is shown in Fig. 8.

Because calls from the different originating offices to the same called office may receive different charge treatment, the tandem billing indexer must first determine which one of the originating central offices is making the call. For this purpose, it has a calling-office code translator for a maximum of 800 central office codes. This translator selects an output code terminal representing the calling office, taking into account the telephone numbering area in which the calling office is located. Since the customers of some originating central offices may be grouped into separate rate classes, with their calls to tandem routed over separate trunk groups, the selected code terminal is subjected to a second stage of selection by the rate-class relays. By crossconnections, the output code terminals are then combined into 50 groups to operate one of 50 originating rate treatment relays. Each of these relays has 75 contact pairs.

Since the charging plan is a function of both the originating and terminating points, the billing indexer also has a called-office code translator for each telephone numbering area to which calls may be bulk-billed. Each of these translators can select one of 800 output code terminals representing the called central office in its area. By crossconnections, these terminals are combined into 75 groups and wired to the input side of the 75 contact pairs on the rate treatment relays. On the output side, a contact pair of an operated rate treatment relay thus represents a unique combination of an originating and a terminating rate treatment. By crossconnections, these output contacts are combined into groups to operate one of nine billing index relays. Of these, eight furnish indexes for bulk-billed calls, and one furnishes the index for toll service statement calls.

Fig. 8 does not show the simplification of the billing indexer's job if all calls to a whole telephone numbering area are toll service statement calls. The transverter recognizes such areas as not being one of the areas for which bulk-billing indexes have to be determined. For these calls, the transverter signals the billing indexer that the terminating area is completely toll, and the billing indexer then furnishes the toll index. A similar simplified way is used to assign the tenth billing index to nonchargeable test calls.

To determine whether the CAMA record should or should not contain details (for certain reasons even bulk-billed calls may be detail-recorded), the output code terminals of the calling office translator are also grouped by separate crossconnections to operate one of ten record pattern or entry combination relays. Through their contacts, these relays provide ten different patterns of association between billing indexes and detail or nondetail recording.

Toll Switching Functions

The foregoing presented the 1956 version of crossbar tandem as if it were still primarily a local tandem switching system. It has, however, far outgrown this scope. As a result of developments in re-

cent years, it has now also become an important member of the long-distance switching system hierarchy.[7-10] In this hierarchy it can operate at the succeedingly higher levels of toll centers, primary centers, and sectional centers, when subjected to certain transmission requirements which will be discussed in the following. Only the highest level of the long-distance switching hierarchy, that of regional center, is barred to it; this level is reserved for the *4A* toll crossbar switching system which embodies the highest grade through-switching features for long-distance intertoll trunks. The advance of the crossbar tandem to these various levels of automatic switching responsibility is made practical by its basic versatility and is dictated, of course, by the various economies it is able to effect.

The first step in the evolution of crossbar tandem as a toll switching system was reported in 1950.[5] This consisted of the use of crossbar tandem as an office for directly terminating long-distance lines from switchboards in distant cities. Over these lines, distant operators could dial or key-pulse directly into crossbar tandem all calls terminating in local offices to which the tandem had completion access. For instance, the addition of toll terminal equipment at Gotham tandem in New York City in 1947 permitted operators from many states of the country to complete calls to approximately 350 central offices in the New York metropolitan area without the aid of inward operators. This method of establishing telephone connections was a major advance in using crossbar tandem switching equipment for speeding completion of out-of-town calls.

DIGIT-HANDLING CAPABILITIES

To handle outward calls headed into the vast nation-wide telephone network and to perform intertoll through switching, a number of important new features have been developed for the crossbar tandem system. Many of these developments were made concurrently with the CAMA developments, and references to this situation were indicated in the foregoing. For example, it was previously brought out that the latest design dial pulse and multifrequency CAMA senders have a 10-digit call storage capacity. Ten-digit capacity is, of course, the first requirement for nation-wide dialing, where the first three digits specify the called area, the next three the called central office in the area, and the last four the number of the called telephone. Incidentally, this example also brings out the fact that, in contrast to CAMA, the development of toll switching features did not generally result in the use of new common control circuits for crossbar tandem; rather, there was a substantial expansion of the capabilities of the sender and marker circuits.

The second important digit-handling requirement for a fully developed toll switching system is the ability to transmit forward toward the call's destination either the same digits it receives or various modifications of these digits. The modifications take one of three forms:

1. Digit deletion: There are situations where the crossbar tandem system receives the full 10-digit national telephone number, but needs to send forward only part of it. For example, if it has direct intertoll trunks to a common control type of toll center of the called area, it need not send forward the received area code. Or, if it has direct trunks to the central office itself in the called area, it can drop both the area and the central office codes. To meet all conditions, crossbar tandem is arranged to permit deletion of the first 1, 2, 3, 4, 5, or 6 digits of a 10-digit number.

2. Code conversion: Under some conditions, the crossbar tandem system has to send forward to the next office substitute digits. Fig. 9 illustrates a typical situation of this type. To reach a terminating toll center via existing step-by-step type of primary centers, and to avoid costly rearrangement of their present trunking patterns, the crossbar tandem may have to convert the area code into other arbitrary digits.

3. Digit prefixing: It may be necessary for the crossbar tandem system to route calls received for its own area to a toll switching office in the adjacent area for completion. In such a case, the crossbar tandem—being in the terminating area—receives no area code, but has to prefix it for use by the adjacent area office to enable the latter to switch the call back. Fig. 10 illustrates this situation.

Fig. 14. Simplified schematic for 6-digit translation

Another version of this situation occurs when the crossbar tandem system has to complete calls in its own area to a toll center via a step-by-step type of primary center. This is illustrated in Fig. 11. Since the toll center needs the full 7-digit local number received by the crossbar tandem for completing the call, and since the step-by-step switches at the primary center use up some digits for routing, the crossbar tandem system must prefix these routing digits to the 7-digit number it receives.

These outpulsing flexibilities reflect new capabilities of both the sender and marker circuits of the crossbar tandem system. The marker's circuitry has been expanded to receive and analyze a great many additional codes and to furnish to the senders additional varieties of instruction for call completion. The sender's circuitry, in turn, has been expanded to execute these new instructions. From the technical standpoint, these new features both in the sender and in the marker have been accomplished by elaborating on existing design techniques rather than by entirely new approaches.

ALTERNATE ROUTING

The same is true of another expanded feature of the crossbar tandem system, namely, the feature of alternate routing. This feature enables the crossbar tandem system to select automatically one of several alternate routes leading toward the destination of a call when the most direct route is busy. It is of special importance in toll switching in that it increases greatly the efficiency of use of the costly long-distance lines with consequent economies. It also provides important service protection when, for some reason, a whole intertoll trunk route fails.

Alternate routing is a natural ability of the marker. As part of its normal operation, it tests the group of outgoing trunks leading most directly to the call's destination prior to making any connection. If all these trunks are busy, it can advance its test to another trunk group in accordance with the wired preference order of its route relays. A limited alternate-routing feature was included even in the earlier version of the crossbar tandem. However, for a high-ranking toll switching system, this original alternate-routing capability had to be expanded, and the 1956 design can choose three alternate routes toward a destination in addition to the most direct route. A highly simplified version of this feature is shown in Fig. 12.

As indicated therein, the called area or central office code received by the marker from the sender results in the selection of a code point which is cross-connected to the first-choice route relay. Each route relay has a number of contacts which are wired to supply all the information to the marker for proper routing of the call. Typical information furnished by the route relay is the type of machine language the sender should use for forward pulsing, the number of digits it should delete, or prefix, or convert, etc. Several of the contacts of these route relays are also used to indicate the number of outgoing trunks to be tested and the location of these outgoing trunks on the crossbar link frames. On the basis of the information from its route relay, the marker tests all of the trunks in the most direct or first-choice route and, if they are all busy, it continues its search for an idle trunk in the first alternate route, the route relay of which is brought into play over the route-advance crossconnection, as shown in Fig. 12.

Like all highly simplified diagrams, Fig. 12 conveys a deceptively simple idea of how the first-choice route relay is operated in the marker. It simply shows a triangle for this purpose labeled "code tree." Especially for completing calls over the nation-wide long-distance network, the operation of the appropriate route relay is a far more complex problem than is apparent from Fig. 12. To operate the first-choice route relay under some conditions of long-distance switching, the marker has to analyze a 6-digit code instead of only a 3-digit code. The need for this new feature, called 6-digit translation, is illustrated by Fig. 13.

When the Belle Plaine crossbar tandem office in Chicago receives a call for a central office in Madison, in the Wisconsin *414* area, and if it only had the ability to select a route relay on the basis of the first three received digits (in this example, the area code *414*), it would have to route this and all other calls destined to this area to the main long-distance switching center of the area, which is the sectional center at Milwaukee. Now, there might be enough telephone traffic from Chicago to Madison to justify direct lines. Routing Madison central office calls over direct lines to the Madison toll office saves trunk mileage as well as eliminates the use of the switching machine at Milwaukee for this traffic. However, to do so requires that the crossbar tandem marker be able to select a first-choice route relay by examining both the 3-digit area code and the 3-digit central office code within the area. Fig. 14 is a simplified schematic of this 6-digit translating feature.

Six-digit translation in crossbar tandem involves the marker and a new control circuit called the "foreign-area translator." This new translator has a capacity for selecting a maximum of 60 separate routings into each of five foreign areas.

On a call, the first three digits received from the sender are used by the marker to select a code point. If a call requires only 3-digit translation, this code point is crossconnected directly to a route relay. If a call requires 6-digit translation, this code point is crossconnected to the proper one of five foreign-area relays. The problem then is to determine which one of a maximum 60 routings into the area should be used to reach the called central office. For this purpose, the foreign-area translator is connected to the marker, and the called-area relay is operated in it. The translator now receives from the sender the second three digits representing the central office code in the called area. By this code, the translator also selects a single code point. Wires from these central office code points in the translator are threaded through transformers which have holes in their centers. There are eight "tens" and eight "units" transformers for each of the five areas. The threading of the wire is through those two transformers for each area that represent the number of the particular routing that the call should take into the area. A current surge sent over the threaded wire, which is, in effect, the primary winding of the transformer, generates a sufficiently high voltage in the secondary winding of the threaded transformers to break down the associated gas tubes. The previously operated area relay in the translator enables the fired gas tubes to operate corresponding "tens" and "units" relays which, in turn, operate their counterparts in the marker. The marker now knows which one of the maximum 60 possible routings to take. The combination of its operated "tens" and "units" relays, through the proper area relay, selects the final code point in the marker which is crossconnected to operate the route relay.

TRANSMISSION ASPECTS

The crossbar tandem is a 2-wire switching system, i.e., it switches only one pair of voice transmission wires over which conversation flows in both directions. Two-wire switching inherently presents more opportunities for objectionable energy reflections or echoes than does 4-wire switching,[11] because of impedance variations that are the result of different calls taking different paths through the office, with varying lengths of cabling involved. The effects of these variations can, however, be minimized to the point where they are not controlling in the assignment of operating losses to the intertoll trunks. This is accomplished by arranging the switching equipment so that the cabling between the various frames of the office is reasonably short and of low resistance, and by building out the capacitance of this cabling to a common value. The balancing networks associated with the 4-wire terminating sets of the intertoll trunks are, in turn, provided with adjustable capacitors for the purpose of balancing this office cabling capacitance.

It is also worth noting that the crossbar tandem system does not include the switching-pad feature which in the past has been widely used in toll switching practice to realize satisfactory singing and echo conditions on each terminating connection. Instead of switching pads, reliance is placed on securing adequate balances between the balancing networks in the intertoll terminating sets and the toll-connecting trunks. To insure this adequate balance, the toll-connecting trunk impedances are improved where necessary, and the short trunks are built out with 2-decibel fixed pads. With the foregoing precautions and adjustments, the crossbar tandem can provide satisfactory transmission performance at all levels of the toll switching hierarchy except at the highest or regional center level.

Conclusion

In spite of its greatly increased capabilities presented in this paper, the crossbar tandem system is not the best switching system for all applications. For example, it is not at all adapted for the largest field of switching system applications, namely, the local central office field. At the other end of the scale, it is no match for the *4A* toll crossbar system in trunk capacity or routing flexibility required at many of the key switching centers of the nation-wide toll network. However, in between these two extremes of the vast Bell System switching system hierarchy, there are a great many positions at the local tandem, toll center, primary center, and sectional center levels for which the crossbar tandem, with all of its new features, is a well-adapted and economical candidate. This is borne out by present Bell System views regarding probable installations during the next decade. According to these views, control switching points, which include all the important long-distance switching points above the toll center level are likely to be of the types shown in Table I.

Table I. Control Switching Points

Type of Switching System	In Service in 1955	Probable for 1965
No. 4 type of toll crossbar	39	58
Crossbar tandem	2	88
No. 5 crossbar	5	53
Step-by-step intertoll	21	59
Other*	1	17
Total	68	275

*Includes types other than Bell and points where type has not yet been determined.

Equally interesting are the present views regarding the probable number of centralized AMA installations by 1965, and the number of main telephone stations that will be served by them, see Table II.

The figures in Tables I and II indicate

Table II. Probable 1965 CAMA Installation

Type of Switching System	Number of Locations	Main Stations Served
No. 4 type of toll crossbar	32	6,800,000
Crossbar tandem	133	21,600,000
No. 5 crossbar	207	3,500,000
Step-by-step	264	7,100,000

convincingly that the crossbar tandem switching system is slated to play a highly important part in rendering good and economical dial telephone service on a nation-wide scale.

The Development of Automatic Manufacturing Facilities for Reed Switches

J. A. HOSFORD
NONMEMBER AIEE

Synopsis: Many unique engineering problems had to be solved before successful automatic manufacturing facilities could be developed to produce high quality reed switches at low cost for the Telephone System. This paper outlines the engineering program that lead to the successful completion of this project.

THE HISTORY of the program to provide high-volume manufacturing facilities for reed switches is of particular interest because it highlights the close association between the final design of a new product and the design of automatic manufacturing facilities to produce it. The design of this switch differs radically from conventional relays and many unique problems had to be solved before successful manufacturing equipment could be developed for this job. From the time of the original conception of the reed switch, it was recognized that widespread application[1] of this improved, general-use switching element would be realized only if it could be manufactured at a very low cost. This objective could be reached only through automatic manufacture. With this in mind, the Bell Telephone Laboratories, in 1950, approached the engineering division of the Western Electric Company on the general problem, outlined their long-range circuit application plans for these switches, and requested that an inter-company program be undertaken to develop the most economical switch design and to find process methods that could be adapted for automatic manufacture. During the following several years, the two engineering organizations worked together very closely. Manufacturing processes were developed that permitted the design of the switch to be reduced to its functional elements. The present-day highly automatic integrated manufacturing machinery for producing the switch is the direct outgrowth of this very successful program.

The dry reed switch as it is known today appears to be about as simple a product as has ever been made. As can be seen in Fig. 1, it consists of an assembly of three parts, two identical reeds and a short piece of glass tubing. The reeds are made of nickel-iron alloy and are gold plated at their contact ends to provide good contact resistance characteristics.

Simple as this product may seem, many unusual engineering problems were encountered during the manufacturing planning stages. Some of these problems were unique and required extensive study before successful solutions were found. Before any new product can find use in the telephone system, it must be capable of being manufactured at a high-quality level and at a cost in line with the older device to be replaced. In the case of the reed switch, it was evaluated against other telephone relays. Basically, the switch performs the same function as the two leaf-spring contacts in the conventional relay and, for this reason, the manufacturing cost goal was established by the known manufacturing cost for two nickel silver leaf springs with their contacts. Upon analysis, this objective turned out to be approximately 1/20 of the cost of other more complex reed switches that were in low-volume production. At this time, the art of manufacturing both mercury and dry reed switches was still relatively new, and the facilities and methods of manufacture were laboratory-life in nature. Switch subassemblies were manually fabricated by loading parts into small jigs, and the success of each operation was dependent to a large degree upon the skill of the operator.

Of equal importance to the low-cost goal, the switch had to be manufactured to very high-quality standards. The electrical characteristics of the switch as determined by its magnetic operate and release measurements had to be held within tight limits, and the entire manufacturing process had to be engineered to assure that all switches would have a reliable long service life. Uniform electrical characteristics required reeds fabricated to very close tolerances, and the machinery and tooling to produce these parts had to be engineered to insure process uniformity. Similarly, the subsequent reed gold-plating and heat-treating operations had to be carefully engineered for process stability.

Unlike conventional relays, the contacts in this switch are not designed to rub or scuff on closure. Contact behavior studies revealed that units with weld-aligned contacts exhibited very long life. Therefore, every effort had to be made to

---

Paper 56-663, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 28, 1956; made available for printing May 8, 1956.

J. A. Hosford is with the Western Electric Company, Inc., Allentown, Pa.

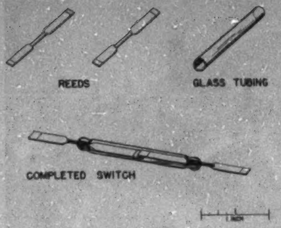

Fig. 1. New reed switch

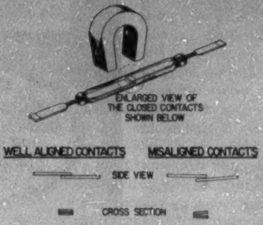

Fig. 2. Contact alignment objectives

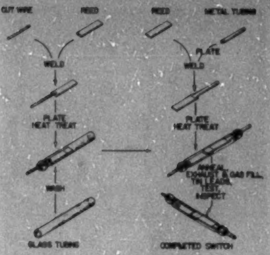

Fig. 3. Old type of reed switch

insure that the reeds in all switches were well aligned, as illustrated by Fig. 2.

To understand better the manufacturing process for glass-enclosed switches, the steps that are followed to assemble one of the older designs of these switches are reviewed. Fig. 3 illustrates one of the typical reed switches that was in limited production at the time this program was undertaken. While this switch is simple in design and contains but five parts, 23 major operations are involved in its manufacture. These include two separate welding operations, four heat-treating operations, three plating operations, two glass-sealing operations employing intricate fixtures, four washing operations, etc. It became obvious that, if the ultimate cost objectives were to be attained, the design of the switch would have to be reduced to its barest elements and a simplified manufacturing process would have to be developed that would lend itself to full mechanization. At the time this project was started, a study was made of all types of automatic machinery employed in the glass-working industry. While several different commercial machines could have been adapted to assemble this type of structure, none were even remotely capable of locating metal elements in glass to the needed accuracy of ±0.0005 inch. It was then realized that it would be necessary to develop a radically new type of assembly machine capable of conforming to the precise needs visualized for the fabrication of switches.

Both the engineering groups involved in this project were aware of these problems and realized that the project would have to be directed accordingly. This program had to be pursued in a logical manner and the work to be done fell into the following four categories:

1. Develop and resolve a suitable manufacturing process.
2. Develop and design automatic manufacturing equipment.
3. Establish final design of the product.
4. Improve and refine manufacturing processes and machinery for high-level production use.

Work was first undertaken to find a manufacturing process that would favor economical production without sacrificing the long life and quality objectives required by the telephone system. After studying all the processes that might be used, detailed cost breakdowns were made for those showing the greatest promise. These studies highlighted the more expensive manufacturing operations and indicated which should be mechanized. One of the more expensive processes revealed by this study was the operation of filling the completed switch with gas. Heretofore switches were gas-filled by one of two methods; neither appeared very attractive for high-level production. The first method employed the bell jar principle where the gas filling was accomplished by performing the glass-sealing operations in a container filled with the desired fill gas. Experience had shown that this process was not well suited to high-level production and had certain inherent process difficulties difficult to correct. The alternative method of gas filling was to use a metal tube as one terminal of the switch. Then after the glass seal was completed, the switch could be placed on a conventional exhaust machine which would cycle to evacuate, gas fill, and weld off the tubing. Inquiries to various suppliers revealed that, even if tubing was purchased in very large quantities, its cost would prevent meeting the switch cost objectives. Thus, it became apparent that an entirely new method of gas filling permitting the use of solid switch terminations would have to be devised. If the air in the switch could be displaced with a suitable fill gas by blowing this gas through the glass tubing during the glass-sealing operations, the need for metal tubing and a welding operation could be eliminated. With the use of such a process, the switch design could be reduced to its barest elements, i. e., three parts—two identical metal reeds and a short length of glass tubing.

After the foregoing assumptions had been made, work was then directed toward developing automatic assembly equipment to determine whether these process assumptions were valid and practical. It was decided that the assembly machine should consist of a number of individual assembly heads mounted on a rotary table. These assembly heads would accurately jig the parts, seal the glass to the reeds, gas-fill the switch, and space the reeds to the desired gap. By building all of the needed accuracy into the assembly heads themselves, the construction of the machine could be simplified and the over-all cost of the machine could be reduced. To eliminate the vibration associated with indexing which, it was felt, was certain to affect the accuracy of the read spacing, it was decided that the machine must have a continuously revolving, rather than indexing turret.

The next step after establishing these general design objectives for the machine was to develop chucks and loading devices which would permit the assembly heads to pick up while in motion all the parts for a switch, i. e., two reeds and a piece of glass tubing. Brass working models of the proposed chucks and loaders were built and mounted on slides to simulate the action of an automatic machine. By working with these models it was possible to modify and improve their design so that they would transfer parts with a high degree of reliability. Work was then started on a complete assembly head. It was decided to design this unit similar to a die set and to build it to very close tolerances to ensure the accuracy of the reed alignment of the completed switch. Fig. 4 pictures the first experimental assembly head. This unit consists of a 3-decked fixture. The top deck holds the chuck for the upper reed. The second deck

holds the glass chuck, and the bottom deck holds the chuck for the lower reed. The two upper decks are lifted vertically by means of a stepped lift rod to permit pickup of the individual switch parts and to insert subsequently the two reeds inside the glass tubing. A pivoted gap-spacing arm located underneath the head causes the lower chuck to move with respect to the rest of the head, thus providing a means for setting the reed gap.

An experimental machine was designed and constructed; see Fig. 5. Parts were manually loaded into a transfer mechanism which swung into position and allowed the head to pick up the two reeds and the glass tubing as it passed by this station; see Fig. 6. Fig. 7 shows a close-up view of the assembly head with the two reeds and glass tubing held in separate chucks. The glass sealing was accomplished with radiant heat from two platinum-alloy coils surrounding both ends of the glass tubing. By passing high current through the coils, a temperature of approximately 1,300 degrees centigrade was attained and sufficient heat was generated to cause the glass to soften and seal around the metal reeds.

By the middle of 1952, work on the experimental machine had progressed to the point where it was possible to assemble a prototype switch. Four different experimental designs of reeds were fabricated and groups of switches were assembled from each of the different types of reeds for statistical evaluation. Mass spectrographic analyses of the residual gas in the completed switches revealed that the gas purity was very high and without a trace of oxygen. Life tests proved that the proposed method for gas filling was satisfactory and could be used in the final machine.

However, checks on the contact alignment in the completed switches revealed that many of the units had poorly aligned contacts; see Fig. 2. Since the reeds used in these experiments had been made by both rolling wire and by coining wire in experimental dies, it was assumed that the alignment difficulty was primarily caused by the crude tooling used to fabricate the reeds. Nevertheless, the analyses of these experimental switches made it possible to freeze the final switch design, Fig. 1, and work was started to design a fully automatic multiple-head assembly machine.

To produce a better reed, a high-speed slide press fitted with a heavy toggle attachment was procured, and production-type dies were built to coin reeds from wire. As soon as this tooling was proved in, switches were fabricated with the improved reeds coined on this machine. These switches still did not exhibit satisfactory contact alignment. A new program was undertaken to improve further the dimensional accuracy of the reeds through better tooling and parts processing. The dies were redesigned with heavier backing plates, improved camming, and carbide punches to withstand

the tremendous coining pressures. These new tools produced very straight and extremely accurate parts but the switches still did not exhibit good contact alignment. The general alignment objectives were, therefore, restudied and, in late 1953, a new sequence for assembling the switch was devised that promised great improvement. Rather than hold the upper reed by its chuck during the glass-sealing operation, it was proposed to close magnetically the two reeds and lease the terminal end of the upper reed by opening its chuck. Because the two reeds would be magnetically locked together in the overlap area, the upper reed could move to mate in perfect alignment with the lower reed. With the upper reed then held in this fashion, the upper glass seal could be made and allowed to cool. Then by horizontally spacing the lower reed away from the upper reed with the use of a parallel motion, the contact alignment in the completed switch could be preserved. To assess this proposal, one of the heads was removed from the recently completed final assembly machine and mounted, together with simulated controls, on a bench. With the use of this head, it was possible to assemble switches by the proposed method without disturbing the complex assembly machine. The results were very promising and action was immediately undertaken to redesign and modify the completed assembly machine to adopt the improved method. Two months later, prove-in runs on the multiple-head machine verified that the alignment problem finally had been corrected, and production of switches was started shortly afterwards.

Perhaps the most interesting of all the development problems encountered during this program was the mechanism for setting the reed gap. The reed switch, like most of the electric components manufactured by the Western Electric Company for the Bell Telephone System, had to be manufactured to specific electrical characteristics. The range for the operate and release requirements which are specified in ampere-turns is narrow, and it was recognized that special steps would have to be taken to ensure that all of the switches made would have characteristics which fall into these narrow bands. As repair operations are not possible on this type of glass-enclosed device, the entire manufacturing process had to be carefully engineered and controlled to make sure that the magnetic sensitivity of the switches would be very uniform and of the correct value.

Fig. 10. Automatic test fixture

Like the experimental machine, the assembly heads in the final machine, Fig. 8, are designed to set the reed gap by moving the lower reed away from the upper reed. The reed spacing is accomplished by pushing the lower end of the gap-spacing arm approximately 1/2 inch, which causes the slide on the lower deck of the head to move approximately 0.010 inch. The chuck which holds the lower reed is fastened to the end of this slide. On the rotary machine the gap-spacing arm is moved when the head travels past a fixed cam. Since the reed spacing is a prime factor in controlling the magnetic sensitivity of the

switch, considerable attention was devoted to this operation. The mechanical details of the linkage in the assembly head were carefully designed and constructed to exacting tolerances. During the prove-in of the multiple-head machine, it was found that minor variations existed between heads and that other machine factors also influenced the reed spacing in the sealed switches. To compensate for these variations, a servo system was then developed to adjust the gap-spacing cam to a different setting for each of the 18 assembly heads. To understand just how this system works, the entire automatic assembly and test equipment now in use on this job will now be reviewed; see Fig. 9. As mentioned before, the assembly machine consists of a clockwise rotating horizontal table on which 18 heads are mounted. The machine and its associated test set work in unison to assemble and test the switches automatically, and they require only part-time operator attendance to fill the supply line and to correct any troubles.

The assembly operation starts when the heads are fully expanded. The reeds are oriented and fed into the assembly machine by two vibratory feed bowls. The glass tubing is fed from a magazine. Transfer heads, not visible in the figure, deliver the parts to the expanded heads as they pass by these loading stations. As the heads close, the glass and reeds are telescoped together and current is applied to the heater coil at the upper end of the glass tubing. When the upper glass seal is completed, the reeds are spaced apart by means of the gap-spacing cam and the glass is then sealed around the lower reed. After the switch has been allowed to cool, the head is expanded and the switch is discharged into a bucket conveyor.

The conveyor, Fig. 9, is geared to the assembly machine and has buckets associated with each assembly head. In this manner, the identity of the switch is carried over to the automatic test fixtures; see Fig. 10. Here, in addition to 100-percent checks on the operate, release, contact resistance, and voltage breakdown characteristics, a test is made to determine whether the operate value of the switch lies above or below the specification nominal, i.e., 90 ampere-turns. This last electrical information is then fed into a memory device, Fig. 11, in the assembly machine control cabinet and is stored in the corresponding one of 18 potentiometers. At the proper time, this stored information is fed back to a servomotor on the machine. This motor adjusts the sliding cam surface which moves the gap-setting arm on the associated assembly head. The servo system functions by comparing the memory potentiometer setting with the position indicator potentiometer on the sliding cam mechanism. The voltage difference between these two potentiometers is amplified and fed to the reversible d-c servomotor, which then drives the system to a null and effects an exact cam setting as governed by the memory potentiometer.

When a switch under test has an operate value below the specification nominal, the reeds are too close together and a mechanism inside the control cabinet automatically adjusts the associated memory potentiometer upwards a small amount to increase the reed spacing on the next switch assembled on that head. Likewise, if the switch under test had an operate value above nominal, its potentiometer is automatically adjusted downward to decrease the reed spacing on the next switch assembled on that head. Thus, corrective test information is continuously fed back into the assembly machine through the memory device in the control cabinet. The system has purposely been designed to sense, interpret, and feed back information for every switch tested. Experience has shown that frequent machine adjustments are necessary because the platinum-alloy heater coils used to seal the glass to the reeds distort and sag at their elevated operating temperature. When these coils shift in position with respect to the glass tubing, the physical shape of the glass seals will change, and the internal stresses which set up in the glass as it cools will cause a slight shift in the reed gap spacing. The feedback system built into the machine senses the resulting change in the magnetic operate characteristics of the switch and adjusts the reed gap in a compensating direction. Since machined adjustments are continuously made as required, all the switches assembled center around the nominal operate test specification.

This development program was pursued over a 5-year period and has provided truly automated facilities that are now annually producing millions of highly reliable glass-enclosed switches for use in the telephone system at 1/20 of their former cost. The results of this project serve to show how research and manufacturing engineering organizations can work together closely to nurse a high-quality product into low-cost volume production.

The Use of Computing Machines in the Statistical Evaluation of Electrical Components

W. E. ANDRUS, JR.
NONMEMBER AIEE

DURING the last few years, the field of applied statistics has experienced a tremendous growth. This is evidenced by the increasing acceptance of the statistician as a vital member of the research and engineering team. The advent of the computing machine is not the least of the factors which has contributed to this growth. Not too long ago, complex statistical problems in multivariate analysis or analysis of variance were beyond the realm of possibility because of the months and years necessary to obtain solutions by conventional hand computation methods. Now, with the existence of computing machines of increased sizes, speeds, and capacities, more of these problems can be solved and are being solved on a routine basis.

Statistics

Applied statistics is a useful tool to the engineer in a number of ways. Statistical evaluations of life characteristics and operating parameters of, for example, tubes, transistors, and rectifiers make the selection of these components and their respective operating limits more precise. This obviously is an aid in the effort to build systems which are more accurate in their function and more reliable in their operation. There is, and always will be, some variation in the characteristics of components and even in the output of a system. If the system variation is excessive, statistical evaluations can determine the sources and differentiate between the contributions of the various components, isolating those sources which have the greatest effect on the output function of the system.

Fundamental Statistical Calculations

The typical statistical problem involves extensive use of rather elementary arithmetical operations. Initially, these operations may be the sums of the data elements or may be the sums of the squares, or specific products of the elements. The sums involved depend to a large extent upon the analysis applicable to the problem of hand. This is usually the first phase of the problem, and once they have been obtained they are used to compute such statistical parameters as the mean, variance, or correlation coefficients.

Take as an example a simple problem in evaluating the pickup time of relays measured at a specific voltage. If a group or a sample of relays is selected at random from a typical production lot and the pickup time of each is measured, a set of data is generated similar to that shown in the following.

Pickup Time, Milliseconds

4.6	4.6	4.5	4.4	4.1
4.5	4.4	4.6	4.9	4.5
4.5	4.8	4.6	4.5	4.6
4.2	4.7	4.3	4.3	4.7
4.8	4.4	4.7	4.5	4.4

$N = 25$ $\bar{x} = 4.52$
$\Sigma x = 113.1$ $\sigma^2 = 0.0361$
$\Sigma x^2 = 512.53$ $\sigma^2 = 0.19$

The well-known average, or mean $\bar{x}$, pickup time is expressed as

$$\bar{x} = \frac{\Sigma x}{N} \tag{1}$$

where x is an individual measurement and N is the number of relays contained in the sample.

The mean, which is perhaps the most widely used statistical measure, is but one of the required values which are necessary to adequately describe a phenomenon. The second, and too frequently overlooked measure, is the standard deviation σ which can be expressed as

$$\sigma = \sqrt{\frac{1}{N-1}\left[\Sigma x^2 - \frac{(\Sigma x)^2}{N}\right]} \tag{2}$$

where σ is the unbiased estimate of the population standard deviation based upon a sample of size N and is a measure of the variation of the data elements about the mean. The two measures then, $\bar{x}$ and σ, are the parameters of the normal distribution which is one of the most important frequency distributions in statistics, since many statistical procedures are based upon it. The use of the normal distribution curve is the same as that of any other distribution curve where the relative frequency with which a variable will take on values between two points is the area under the curve between the two points on the horizontal axis. The term "normal distribution" in this case refers to the fact that the area under the curve is distributed in a specified manner.

Consider Fig. 1, which is a histogram of the data in the foregoing table. The height of the shaded columns shows the frequencies or number of measurements which had a specific value of pickup time x. The smooth curve drawn through the histogram is that of a normal curve and it is evident in this case that the curve approximates the distribution quite well. Fig. 2 denotes some of the properties of the normal curve consistent with statistical theory. As an example, the area under the curve between $\bar{x} \pm 1\ \sigma$ is 67% (per cent). Thus the probability is 67% that a relay selected at random will have a pickup time between $\bar{x} - 1\ \sigma$ (4.33 milliseconds) and $\bar{x} + 1\ \sigma$ (4.71 milliseconds) or that, on the average, 67% of the relays measured will fall within this interval. Correspondingly, the area between $\bar{x} \pm 3\ \sigma$ is 99.7% and, on the average, only three times in a thousand will relays of this type have a pickup time greater than $\bar{x} + 3\ \sigma$ (5.09 milliseconds), or less than $\bar{x} - 3\ \sigma$ (3.95 milliseconds).

Frequently, a determination of the accuracy of the sample mean as an estimate of the population mean is dewired. In this case the population is the total production of this type of relay. Sample means are distributed about the population mean (μ) normally with a standard deviation ($\sigma_{\bar{x}}$) determined by

$$\sigma_{\bar{x}} = \frac{\sigma}{\sqrt{N}} \tag{3}$$

where $\sigma_{\bar{x}}$ is the estimated standard deviation of sample means and σ is the population standard deviation estimated from the sample by equation 2. For the example of relay pickup times, $\sigma_{\bar{x}} = 0.038$ millisecond, and there is a probability of 95% that the sample mean $\bar{x} = 4.52$ does not differ from the population mean by more than ±0.076 millisecond.

Statistical Programs

The foregoing example of relay pickup times is not only representative but also serves to illustrate computing techniques and statistical program organization. Note that three basic quantities were re-

quired from the data, namely N, $\Sigma\, x$, and $\Sigma\, x^2$. These are the summations mentioned previously and once they are obtained, the original data are not used again for the remainder of the analysis.

The solution of this type of problem then may be separated into two phases. The first phase, in which the required summations are accumulated, is designated as "data reduction." The second, in which the summations are used in the solution of certain equations, is designated "analysis." The computer programs to solve these problems are written in such a way that it is possible to separate the two sections when desired. This is particularly true if the programs are written for a "library" in which they are kept on file and used for subsequent problems.

The discussion of statistical programs will be limited primarily to the IBM (International Business Machine) type-*650* magnetic-drum data-processing machine; see the Appendix. However, mention will be made of another larger computer, the IBM type *701*, which is used to advantage for specific problems of a larger scope.

Return now to the example of relay pickup times. There are many ways in which the data reduction section of this problem may be organized, but for this discussion assume that the data are recorded in punched cards, one data element x per card. Accordingly, the program requirements are that on each card read into the computer the value x is added first to a running sum $\Sigma\, x$, and then squared and added to a running sum $\Sigma\, x^2$. Additionally, the number of cards is counted, and thus the number of data elements, by adding a 1 to the count for N. After all of the data cards are read into the computer the sums are either punched into an output card or stored in memory for subsequent reference.

Since a particular problem might involve a number of groups of data, each group is identified by a problem code and group number, by inserting behind each group of data cards a "distribution control card." When this control card is detected, the summations and identifying designations are punched into an output card. The memory locations containing the summations are then restored to zero to prepare for the accumulations of the next group of data. The output card containing the summations is read into the computer with the analysis program and the parameters $\bar{x}$, σ, are computed and punched into another output card. There obviously are many ways in which programs of this nature may be organized. One significant variation could be to perform the desired analysis after each distribution control break. In doing so, the reading of the summation cards back into the computer would be eliminated.

DISTRIBUTION ANALYSIS

The statistical calculations discussed thus far are usually classified as "distribution analysis." Problems of this nature involve the description of a phenomenon by frequency distributions and polygons, and the estimation of certain characteristics of the population. This is perhaps the most basic type of statistical problem but it is the foundation upon which more complex analyses are based. Thus far only normal distributions have been considered. Since many of the distributions encountered cannot be approximated by the normal distribution, it is advisable to incorporate a normalcy test into the analysis program. One method of performing this test is to compute the index of skewness α_3 a measure of the symmetry with respect to the vertical axis through the mean, and the index of kurtosis α_4 describing the "peakedness" of the curve. For normal distributions, α_3 and α_4 should be very nearly zero. A second method would be to perform a "chi square goodness-of-fit" test in which the observed relative frequencies are compared with the expected relative frequencies for significant deviation. The indexes of skewness and kurtosis are easily obtained by additional program steps in the data reduction and analysis programs. The chi square test, in this case, is less convenient, since the data must be stored in the machine or read into the machine twice in order to perform the necessary comparisons.

It is good practice to include procedures which verify the resulting summations. This can easily be done by including another sum in the data reduction program. If $\Sigma\,(x+1)^2$ is accumulated, it is possible to compare the other sums with it by the identity

$$\Sigma(x+1)^2 = \Sigma x^2 + 2\Sigma x + N \tag{4}$$

or, in the case of the sum necessary for the tests of normality which require Σx^3 and Σx^4

$$\Sigma(x+1)^4 = \Sigma x^4 + 4\Sigma^3 x + 6\Sigma x^2 + 4\Sigma x + N \tag{5}$$

These tests may be incorporated as part of the data reduction or analysis programs.

The distribution analysis programs may take other forms. One which has already been discussed is the determination of the parameters $\bar{x}$, σ, of normal distributions and the indexes of skewness and kurtosis. A further analysis is the cumulative frequency distribution, Fig. 3, which denotes the probability with which observations will fall to the left of any specified value. This type of analysis is particularly valuable to the engineer since it allows freedom as to the selection of probability levels. As an example, 4.2 milliseconds corresponds to a probability of approximately 5%. Thus, 5% of the relays will have a pickup time of less than 4.2 milliseconds and 95% greater than 4.2 milliseconds. The curve is, in effect, the area under the normal distribution curve from minus infinity to the specified point. These areas have been tabled for the normal distribution for values of Z determined by

$$Z = \frac{x_i - \bar{x}}{\sigma} \tag{6}$$

where x_i is the specified point. By using equation 6, x_i in data units is converted to

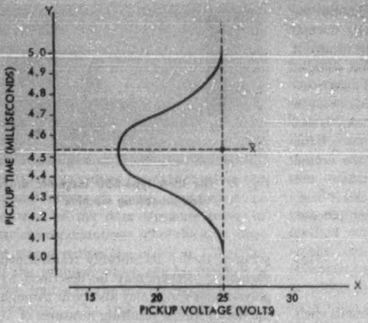

Fig. 4 (left). Distribution of relay pickup times at 25 volts

5. BRUSH ANGLE	20° 30° 40°
6. TIMING	

Fig. 6 (right). Variables affecting performance of card-reading brushes

Z, standard units, and one table of areas will serve for all values of $\bar{x}$ and σ. The table of areas may be stored in the computer and with suitable programming the areas determined and punched into output cards for incremental values of x_i.

One of the uses of this type of analysis could be in establishing the performance limits for specific relays. In the example, relays of this type could be restricted to use in circuits which have a timing requirement of 5.2 milliseconds or more. In selecting 5.2 milliseconds it is reasonably assured that only one in 2,000 relays could possibly give trouble when used in this application.

Studies of rectifier characteristics, i.e., forward voltage drop or reverse leakage current, are best accomplished by distribution analysis. Transistors, which are subject to wide variations, also fall into this category. The characteristics of these and other components are best described by their distributions; not only for an accurate description but because, as will be seen in the next section, valid comparisons between manufacturers, operating conditions, or usage are now possible.

Tests of Hypotheses

Problems which are classified under "tests of hypotheses" concern comparisons of two or more items to establish which has the more desirable characteristics. By definition, a statistical hypothesis is a proposed theorem concerning some universe or population of individuals. The process of using a sample to "test" whether the hypothesis is true (or false) is called a statistical proof of the truth (or falsity) of the hypothesis. As an example, the pickup time of one type of relay might be compared with that of another, or rectifiers from one manufacturer compared with those of another, to determine which has the better characteristic. Tests of comparison such as these can best be accomplished by statistical methods.

Consider as an example two groups of rectifiers, each the product of a different manufacturer. The forward voltage drop is measured for each rectifier and the mean and standard deviation of this measurement is determined for each manufacturer. If $\bar{x}_1$ σ_1 are the estimated parameters of the distribution describing the forward voltage drop for the rectifiers from one manufacturer and $\bar{x}_2$, σ_2 for the other, it is possible to determine the significance of the difference between the samyle means. This test, called the "student's test," is expressed as

$$t=\frac{\bar{x}_1-\bar{x}_2}{\sigma_p}\sqrt{\frac{N_1\times N_2}{N_1+N_2}} \tag{7}$$

where

$$\sigma_p=\sqrt{\frac{(N_1-1)\sigma_1^2+(N_2-1)\sigma_2^2}{N_1+N_2-2}} \tag{8}$$

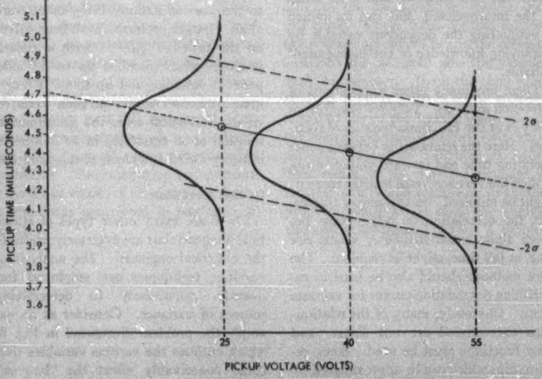

Fig. 5. Linear regression: relay pickup time versus pickup voltage

The statistic t is a measure of this difference for which probability tables have been tabulated. For a particular value of t the tables indicate the probability that the two samples, came from the same population; or that the difference exhibited by the means is significant. A casual examination of equation 7 indicates that t is dependent upon σ_p, a measure of the pooled variation of the data. Consequently, the difference between the means $(\bar{x}_1 - \bar{x}_2)$ may or may not be significant depending upon the uniformity of the measured data and a valid comparison is possible only if the measured characteristic is described by the two parameters, $\bar{x}$, σ.

Another type of test is a comparison of the uniformity of the rectifier characteristics by manufacturer. In this case the test is a comparison of the σ's for each manufacturer and determines whether one manufacturer's product is more uniform than the other. These and other tests are actually the comparison of the distributions, and the input data for computer programs which perform them are the parameters of the distributions. Consequently, programs which handle these problems are the natural extension of distribution analysis programs.

REGRESSION ANALYSIS

Another type of analysis, which is extremely valuable to the engineer and which is handled well by computing equipment is described as "regression analysis." Problems in this area involve the determination of the functional relationships of one variable against one or more others.

Return once again to the distribution of relay pickup times. The distribution was described by a normal curve from which certain information was obtained. Since this was the distribution for relays measured at 25 volts, it can be figuratively rotated 90 degrees as shown in Fig. 4 and a different relationship can be visualized, namely, the effect of voltage. If the pickup time for the same group of relays was measured at 40 volts and again at 55 volts, there would result three distributions as shown in Fig. 5. A straight line drawn through the means shows that there is a linear relationship between the variables, pickup time y and voltage x, and may be expressed as

$$y = a_0 + a_1 x \tag{9}$$

where a_1 is the slope and a_0 is the intercept. Knowing the coefficients of this function it is now possible to predict the mean pickup time for some other voltage, say 35 volts.

Under actual testing conditions the distributions are never perfectly normal as shown in Fig. 5, nor will the means of each distribution fall on a perfect straight line. Accordingly, the method used in establishing the best straight line or even the best function if the relationship is not linear, is that of least squares in which the squares of the deviations of the actual measurements from the function are minimized. In the linear case this is basically the solution of the simultaneous equations

$$a_0 N + a_1 \Sigma x = \Sigma y \tag{10}$$

$$a_0 \Sigma x + a_1 \Sigma x^2 = \Sigma xy$$

The computing load for problems such as these can be quite heavy for any appreciable amount of data, and the computing machine may be used to good advantage. A problem consisting of 100 measurements of (x, y) can be completely solved on the type *650* in approximately 40 seconds. The programming is again broken into the data reduction and analysis phases for flexibility. The input data are recorded, an (x, y) pair to a card, where x is the voltage and y the pickup time. The data reduction program accumulates the sums required in equation 10 and punches them into an output card. When the output card is re-entered into the machine, suitable analysis programs will solve the simultaneous equations 10, for a_0 and a_1, determine the correlation coefficient r, which may be expressed by

$$r = \frac{N\Sigma xy - \Sigma x \Sigma y}{\sqrt{[N\Sigma x - (\Sigma x)^2][N\Sigma y^2 - (\Sigma y)^2]}} \tag{11}$$

and compute various other values which are indicative of the relationship between the variables. The correlation coefficient r measures the degree of association between the two variables and is an index of the improvement that can be gained in estimating the dependent variable by employing knowledge of the independent variable.

There are many other applications of regression analysis. Take for example an analysis of the life characteristics of rectifiers. Here the relationship between pulse operating time and forward voltage drop, or shelf life versus reverse leakage current, might be required. In the case of transistors the correlation or relationship between alpha cutoff frequency versus rise time, or fall time, might be required. The same methods should also be used in establishing degradation curves for vacuum tubes. Obviously, many of the relationships encountered are not linear, and other functions must be used. Some relationships which can be approximated by exponential functions, may use linear regression theory on suitably transformed variables. Others may be described by polynomials which may also be fit through the data with the resulting measures of fit and dispersion.

Fig. 7. The IBM type-650 magnetic drum data processing machine

A further extension of regression theory concerns problems which involve more than one independent variable. These are multiple-regression problems, which have many applications. As an example, a third variable, namely pre-energization time, could be added to the example of relays. Here a voltage is applied across the relay prior to the actual pickup voltage but of low enough value so as not to pick up the relay The analysis now determines the relationships of pickup time versus various levels of pickup voltage and pre-energization times, and the describing function is a plane, or a surface For the linear case the describing function is expressed as

$$y = a_0 + a_1 x_1 + a_2 x_2$$

where the coefficients are determined by solving the simultaneous equations

$$a_0 N + a_1 \Sigma x_1 + a_2 \Sigma x_2 = \Sigma y$$
$$a_0 \Sigma x_1 + a_1 \Sigma x_1^2 + c_2 \Sigma x_1 x_2 = \Sigma x_1 y$$
$$a_0 \Sigma x_2 + a_1 \Sigma x_1 x_2 + a_2 \Sigma x_2^2 = \Sigma x_2 y$$

This type of problem can be extended to tremendous size involving many variables. Larger problems have been solved on the type-*701 EDPM* with a general program which handles up to 50 independent variables and up to 1,022 5-decimal digit observations of each variable. In the maximum case, the simultaneous solution of 50 equations in 50 unknowns is incorporated as a phase of this program.

OTHER ANALYSES

There are many other types of statistical analyses that are extremely useful to the electrical engineer. The analysis of variance techniques are employed frequently, particularly in determining sources of variance. Consider as an example the problem illustrated in Fig. 6, which outlines the various variables that could conceivably affect the "bounce" of card-reading brushes. The question to be answered is which factor or combination of factors has the greatest effect on brush bounce and thus which should be controlled more closely in order to minimize this troublesome characteristic.

A general program for the type *650* has been developed to handle problems of this nature which are complete factorial designs. Since the computing necessary to reduce the data involves the accumulation of sums, and sums of squares, of the data elements taken in various combinations, all of the data must be stored within the machine. The size of the problem which can be handled is thus limited by the storage capacity of the computer. The type *650* can accommodate as much as 16,500 digits of data with the remaining 3,500 digits (350 10-digit numbers) containing the program. As an example, a 5-factor analysis involving five variables at 3, 4, 5, 6, and 7 levels contains 2,520 observations. If the observations are in 4-digit numbers, there are 10,080 digits and the problem is well within the capacity of the machine. The *650* computes all of the necessary sums of squares by summing over the variables 1, 2, 3, 4, and 5 at a time, and punches these values and the corresponding values of n, into an output card. An additional program converts the sums of squares into mean squares and tests, each with the residual to determine which of the main effects and interactions are significant. Another problem solved recently was a 5-factor analysis involving some 3,000 observations which took approximately 7 hours to compute on the type *650*. This compares with a period of many days required for a solution by conventional hand computation methods.

Another type of analysis used quite extensively employs the auto-correlation and spectral-density functions. These functions determine the presence and magnitude of periodicities exhibited by data which might, for example, describe the performance of an electronic system. One particular problem which was computed on the type *701* considered 1,290 discrete measurements of the performance of an aircraft under adverse wind conditions. The computing and printout of the 1,289 values of the auto-correlation function was completed in less than 30 minutes

Statistical Program Library

The use of high-speed computers is justified without question for problems involving either large numbers of data or extensive numerical manipulation. Problems of a smaller nature may also be handled efficiently by the creation and maintenance of a program library. Programming, coding, and "debugging" account for more than half the time and cost of machine computation, and any method which reduces these items increases the usefulness and value of the computing activity. The program library, in which programs are kept on file and used when appropriate, is but one of the procedures which increases this usefulness.

The general program library usually contains programs which solve simultaneous equations, determine the roots of polynomials, and evaluate transcendental functions such as square roots and logarithms. These programs are classified as subroutines since they may be inserted into and made part of the over-all program for the solution of a particular analytical problem. Many of the programs kept on file perform a complete analysis and may contain a number of the subroutines. Programs for the solution of statistical problems form a unique library because a great many of the analyses may be used over and over again on problems ranging from microsecond timing analyses to million-dollar inventory distributions. The availability of a library such as this permits the use of computers economically for the smaller type of problems which could not otherwise justify their use.

The programs of a type-*650* library may be made compatible with one another by the use of program transfer control cards. These cards contain instructions which are stored in specific memory locations and are read into the machine with the program. Upon the completion of each program, the control is transferred to one of the specific locations and the instruction that is present determines the next phase of the computer procedure. This might be to stop the machine or transfer to a punch routine or to another program which would carry the analysis through an additional phase. A problem is prepared for the computer by the proper selection of library programs and program controls which are deemed necessary.

Conclusions

The computing machine has become a necessary tool in the research and development laboratory and has made possible many of the recent technological accomplishments. Mathematical statistics is also a necessary tool and has become a recognized part of machine development at the IBM engineering laboratories. The correct utilization of these and other technical tools leads to a reduction in the drudgery of routine calculations and to improved utilization of engineering and scientific personnel.

Appendix

The IBM type-*650* magnetic-drum data-processing machine is a stored program, modified single-address, decimal computer with a drum capacity of 2,000 10-digit numbers. A typical computer installation is shown in Fig. 7. The central unit contains the drum storage, the control circuitry, and the arithmetic unit. The unit to the rear contains the power supply, and the circuitry which converts from the decimal number system used in input-output to the biquinary system used internally. The input-output unit housing the card reader and card punch is shown in the foreground. The maximum reading rate is 200 cards per minute and the maximum punching rate is 100 cards per minute. Input and output data are read through a buffer storage which enables the type-*650* to read, punch, and calculate simultaneously.

The 2,000-word magnetic drum is composed of 40 bands each with 50 words of storage. Each word of storage, specified by a 4-digit address, can be used to store data or an instruction word. The average access time to any location is 2.4 milliseconds.

Instructions to the computer are 10-digit numbers (XX|XXXX|XXXX) called instruction words. The first two digits specify one of 44 possible arithmetic or logical operations. The next four digits, the data address, specify the location of the data to be processed, and the last four digits, the instruction address, specify the location of the next instruction word to be interpreted by the *650*. The addition of two 10-digit numbers is achieved in 5.2 milliseconds and the multiplication of two 10-digit numbers requires 9 milliseconds.

AN ANALYSIS of the process of magnetic recording of digital data is presented from which qualitative design concepts are developed and their usefulness demonstrated, both in the evaluation of magnetic head structures and in their design for high-density storage.

This work was initially undertaken in connection with the development of the International Business Machines *350* magnetic-disk storage file where rather stringent requirements necessitated a program directed towards improving the performance of the existing magnetic recording unit. The external constraints imposed on this work essentially limited the design parameters to those concerned with the magnetic head, excluding the gap dimension. The investigation of this subject led to the development of an analytical formulation of the process of magnetic recording which is directly applicable to data recording. The insight derived from the theory and its relative simplicity in application will be demonstrated through its successful employment in guiding head-design development in connection with the International Business Machines *350* magnetic-disk project.

First, a general discussion of magnetic data recording is briefly presented, stressing the form of the read-back wave form and its relation to bit density. Then the basic theoretical development is presented and the significance of these expressions to magnetic head design is stressed. Experimental results and their correlation with the theory are given, followed by a description of the selected magnetic head for the magnetic-disk file and its performance.

Data Recording

Magnetic recording of data involves the storage and processing of binary information, utilizing two states which are capable of being differentiated. For convenience, consider NRZ (nonreturn-to-zero) recording in which the storage surface is continuously saturated during writing, in one direction for a "1" and in the opposite sense for a "0." A particular input is then composed of a succession of alternating step changes in writing current. Reading involves a derivative-type action, as indicated schematically in the following, which illustrates the over-all transfer process from input to output. The surface co-ordinate is x, and $\mathfrak{x}$ represents the variable indicating the position of the specified surface magnetization relative to the magnetic head

$$i(t)—\mathbf{M}(x)—\phi_h(\mathfrak{x})—vNd\phi_h/d\mathfrak{x}=e(\mathfrak{x})=e(vt)$$

where

$\mathbf{M}(x)$ = distribution of magnetization set up in the storage surface
$\phi_h(\mathfrak{x})$ = reading coil flux as a function of surface position
e = open-circuit read-back voltage
N = number of turns on the reading coil
v = surface velocity
t = time

Hence, $e(vt)$ is a pulselike signal for a step change in $i(t)$,[1] and the surface velocity appears as a scaling factor in both time and amplitude for the output signal. An output voltage signal is then associated with each change in the direction of saturation or reversal in writing current.

Consider the output signals for arbitrary input patterns consisting of sequences of alternating step changes in writing current. On read-back, the existing magnetic field, that was caused by the recorded magnetization of the surface, is extremely weak and, hence, the magnetic head will behave very nearly as a linear element. Further, writing definition or the width of a saturation transition region is much less than the corresponding reading resolution, because of the nonlinear surface saturation characteristic. Thus, generally, reading will limit density before the point is reached at which adjacent changes in surface state modify one another. These considerations imply that the principle of superposition may be applied to the over-all input-output transfer process with the use of the characteristic step function output response. The width and wave form of this characteristic response are thus extremely important, and such responses will be shown as functions of x, or distance, as only in this manner are they meaningful. As indicated in the foregoing, the velocity enters only as a scaling factor between distance and time, and only spatial relations are significant in this recording process. It is evident that bit density considerations will follow directly.

Consider a symmetrical voltage pulse response with a base width of λ. The maximum bit density permissible where no mutual interference is to be allowed, i.e., each saturation change is to be resolved independently, is then equal to $1/\lambda$. On the other hand, if the requirement is only that no pattern modulation occur, implying no signal peak variation, then the bit density will have a limit of $2/\lambda$.

A typical response signal is shown in Fig. 1. The base-line character (or wave form) is quite important, as well as pulse widths at various levels above the base line, in density considerations. The overshoots may be broader than the main pulse. Thus, there is no single criterion that can be used in comparing responses.

A general objective for high-density design is to attempt to obtain a spike-like characteristic output signal, i.e., to eliminate base line signal and maximize the rate of approach of the signal to the base line. Considering undesired signal as noise, the overshoots tend to limit the signal-to-noise ratio at lower densities and first cause overlapping of signals as the bit density is increased. However, even with no base line signal, as the bit density is increased and, correspondingly, a spacing reduction between adjacent sampling strobes, errors will arise with an isolated pulse signal because of the gating of strobes on either side of the strobe which is actually associated with this output indication. This limitation is accentuated by pulse responses with gradual base line approaches and can severely limit performance.

The same considerations apply when the basic input wave form is a discrete pulse rather than a step. The characteristic response in this case will be that from a single pulse input, provided that the resultant recorded dipoles are independent. This case will also be treated.

Paper 56-695, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 8, 1956; made available for printing May 1, 1956.

Theory

In addition to the principle of superposition, the principle of reciprocity is used, these forming the basic tools in this analysis. The applicability of the principle of reciprocity to read-back follows as an immediate extension from the justification for utilizing the principle of superposition. As employed here, the concept of reciprocity states that the magnetic field **H** set up by energizing the reading coil with a small current (assuring low field levels appropriate to read-back and, likewise, the same linear behavior) gives a measure at each space point of the degree of coupling existing between a weak magnetic field source at that point and the reading coil.[2] The space points of concern are those that constitute the magnetic sources on read-back, i.e., the storage surface, primarily the track passing under the transducer but also including nearby adjacent tracks.

A reasonable simplification for the objectives desired, in view of the nature of the problem, is to neglect variations with surface layer depth. This is equivalent to considering the surface as a relatively thin film, which is often the case. The depth factor will be treated later. Then functions defined along the surface depend only on one variable. The centerline of the magnetic head gap (ring structures) is, henceforth, chosen as the fixed reference point, i.e., $\bar{x}=0$.

Then

$$\phi_h(\bar{x})=\phi_{hx}(\bar{x})+\phi_{hy}(\bar{x}) \tag{1}$$

where the subscripts denote the reading coil flux contributions arising from each of the two possible components of surface magnetization $\mathbf{M}_x$ and $\mathbf{M}_y$, when a conventional ring-type transducer is used. The y co-ordinate is normal to the surface, defined positive in the direction of the magnetic head. First only a single track will be considered. The fringing field set up along the storage surface track when the reading coil is energized in the manner described for the reciprocity relation will have the vector components $\mathbf{H}_x(\bar{x})$ and $\mathbf{H}_y(\bar{x})$. Then, according to the principle of reciprocity, $\mathbf{H}_x$ is a function giving the sensitivity of the reading coil to horizontal surface magnetization and $\mathbf{H}_y$ gives the reading coil sensitivity to vertical magnetization.

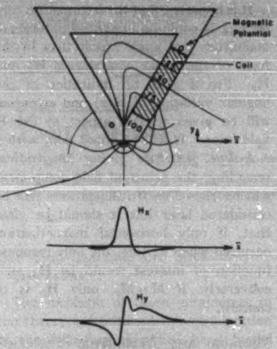

Fig. 3. Field plot showing influence of coil location on H_x and H_y

It can be shown, see Appendix, that

$$\phi_h(\bar{x})=K\int_{-\infty}^{+\infty}\mathbf{M}(x-\bar{x})\mathbf{H}(x)dx \tag{2}$$

where **M** and **H** are vectors combined by a scalar or dot product operation.

Then

$$\phi_{hx}(\bar{x})=K\int_{-\infty}^{+\infty}\mathbf{M}_x(x-\bar{x})\mathbf{H}_x(x)dx \tag{3}$$

and

$$\phi_{hy}(\bar{x})=K\int_{-\infty}^{+\infty}\mathbf{M}_y(x-\bar{x})\mathbf{H}_y(x)dx \tag{4}$$

where the limits of integration are in practice only for the range over which $\mathbf{H}_x$ and $\mathbf{H}_y$ are significant. K is a constant proportional to the surface thickness, if uniform saturation throughout the surface layer is assumed.

Now to clarify the import of these equations, consider an idealized case where $\mathbf{M}_y=0$ and where there is a step change in horizontal magnetization $\mathbf{M}_x$ from $-\mathbf{M}_s$ to $+\mathbf{M}_s$. Then

$$\phi_{hx}=2K\mathbf{M}_s\left[\int_{\bar{x}}^{\infty}\mathbf{H}_x(x)dx+\int_{\bar{x}}^{-\infty}\mathbf{H}_x(x)dx\right] \tag{5}$$

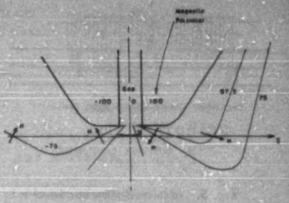

Fig. 4. Influence of narrow pole tips on the weighting function H

and as

$$e(\bar{x})=vNd\phi_{hx}/d\bar{x}=KvN\int_{-\infty}^{+\infty}\mathbf{H}_x(x)\times\frac{\partial\mathbf{M}_x(x-\bar{x})}{\partial\bar{x}}dx \tag{6}$$

then,

$$e(\bar{x})=e(vt)\ \alpha\ v\mathbf{H}_x(\bar{x}) \tag{7}$$

This relation states that the output voltage or pulse response wave form will resemble in time the static field distribution function $\mathbf{H}_x$; i.e., the signal amplitude for a given position of the step change in magnetization relative to the magnetic head gap center line will be proportional to $\mathbf{H}_x$, a weighting function, at that point. Similarly, the output signal arising from a recorded step function change in $\mathbf{M}_y$ would be

$$e_y\ \alpha\ \mathbf{H}_y(\bar{x}) \tag{8}$$

where the subscript on the output voltage indicates that this contribution is due to $\mathbf{M}_y$. Where both components of magnetization exist, the two output signal components may be algebraically added to give the output voltage wave form for $e=e_x+e_y$.

PULSE RECORDING

When discrete pulses are used for data recording, the characteristic voltage response may be related to the sensitivity or weighting functions in the following manner. The magnetization is assumed to be entirely longitudinal, and the following idealized recorded dipole is to be produced by an input current pulse; see Fig. 2.

One direct method for obtaining the characteristic output signal would be to consider merely the recorded pulse as composed of two step function changes in magnetization and to derive the resultant output signal by superposition. However, as will generally be the case, if s is small compared to the width of $\mathbf{H}_x$, then the following approximation may be made, revealing somewhat more clearly the nature of the output signal.

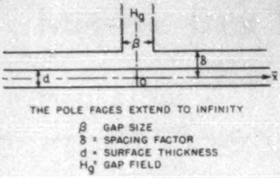

Fig. 5. Idealized magnetic head

The actual $\mathbf{M}_x$ pulse may be replaced by a recorded impulse of the same pulse area. With the use of the relation which exists between the responses to a step function and impulse function in a linear system, the following equations can be written

$$e = e_x$$

and

$$e_x \propto s d\mathbf{H}_x/dx \qquad (9)$$

The characteristic read-back wave form for discrete pulse recording is then seen to be proportional to the derivative of the weighting function and, hence, to the derivative of the characteristic signal obtained when a step function input is used $\mathbf{M}$, being equal to $\mathbf{M}_x$ in both cases.

DETERMINATION OF H

A rapid way to get estimates for the sensitivity or weighting functions $\mathbf{H}_x$ and $\mathbf{H}_y$ is to make rough field plots for the gap fringing field. For this purpose, the magnetic head may be regarded as possessing an infinite permeability. There is no concern about local saturation effects since these maps are to apply for very weak fields. Qualitative information is generally adequate, and normally fine detail would not be justified. It will be seen however that, in general, a factor such as reading coil location is extremely important. The estimates for these fields from such mapping indicate their important qualitative features and these have been confirmed by a powder pattern technique of field observation.

Figs. 3 and 4 show ring-type structures and qualitative determinations of weighting functions, illustrating the importance of coil location and pole-tip shape. The magnetic potential lines shown in Fig. 3 do not, of course, actually apply within the coil or current source region. The orientation of the fringing field vector along the surface, as indicated in Fig. 4, shows the influence of narrowed pole tips in reducing the base line width (neglecting overshoots) of $\mathbf{H}_x$.

It is apparent that the information concerning $\mathbf{H}$ could be presented in terms of magnitude and angle rather than in the form of the scalar components $\mathbf{H}_x$ and $\mathbf{H}_y$. Fig. 4 gives an indication of the angular variation of $\mathbf{H}(x)$ and attention will be given to this aspect of the $\mathbf{H}$ field later. It will be noted that, with a ring-type structure giving longitudinal recording, the principal field component will be $\mathbf{H}_x$. The writing process will be considered later but it should be clear that, if only horizontal magnetization occurred when writing, the only response function of interest would be $\mathbf{H}_x$ and, conversely, if $\mathbf{M}=\mathbf{M}_y$, only $\mathbf{H}_y$ is of concern.

VOLTAGE AND WEIGHTING FUNCTION INTEGRALS

Certain statements may be made about the output voltage-time pulse area, other than its independence of v, in terms of the weighting functions $\mathbf{H}_x$ and $\mathbf{H}_y$. Consider a step change in $\mathbf{M}_x$ from $-\mathbf{M}_s$ to $+\mathbf{M}_s$. Then

$$\phi_h(-\infty) = K\mathbf{M}_s \int_{-\infty}^{+\infty} \mathbf{H}_x(x)dx \qquad (10)$$

and

$$\phi_h(+\infty) = -K\mathbf{M}_s \int_{-\infty}^{+\infty} \mathbf{H}_x(x)dx \qquad (11)$$

Thus, if

$$\Delta\phi_h = \phi_h(-\infty) - \phi_h(+\infty) \qquad (12)$$

$$\Delta\phi_h = 2K\mathbf{M}_s \int_{-\infty}^{+\infty} \mathbf{H}_x(x)dx \qquad (13)$$

but, of course

$$N\Delta\phi_h = \int_{-\infty}^{+\infty} e(t)dt$$

Hence a relation is seen between the output signal voltage-time area and the area under the corresponding weighting function. This immediately gives some insight into the possible degree of overshoot area to be expected. Further, it reinforces the arguments for the importance of reading coil location since, if the coil is so oriented that a uniform horizontal flux field tends to give zero flux linkages, then the negative overshoot area must as a consequence be of the same size as the main pulse area; this applies here to both the weighting function and the output signal which would be proportional.

These same considerations can be as simply extended to an $\mathbf{M}_y$ magnetization component, involving a consideration of the $\mathbf{H}_y$ function.

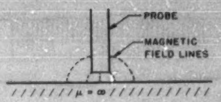

Fig. 6. Field pattern for vertical magnetic probe

ADJACENT TRACK PICKUP

The sensitivity of the magnetic head to adjacent track magnetization can be considered with the use of the reciprocity principle in the same manner as described, both with and without intertrack shielding. Let z be the transverse co-ordinate, and let $z=0$ at the given track and $z=z_1$ at an adjacent track. Note that, since $\mathbf{H}_x(z)=\mathbf{H}_x(-z)$, the worst case for two adjacent tracks, one on either side of the magnetic head, would arise when both were similarly recorded. Now, $\mathbf{H}_x(\bar{x})$ at $z=z_1$ is not only considerably reduced in amplitude over its value at $z=0$ but its relative extent is considerably greater. Since the changes in surface saturation along a track must be alternating, then, as the density of these saturation changes increases, there will tend to be a greater and greater effective cancellation of the individual signal contribution. Thus, because of the low resolution of a magnetic head with respect to neighboring tracks, the lower density patterns are the most troublesome.

FINITE REGION FOR SURFACE MAGNETIZATION CHANGE

An approach to an estimate for the significance of neglecting the actual surface magnetization and using an idealized step function change will be indicated by assuming that $\mathbf{M}=\mathbf{M}_x$ and the change in saturation from $-\mathbf{M}_s$ to $+\mathbf{M}_s$ occurs over the distance x_1 in a uniform manner. Let ρ equal the effective width of $\mathbf{H}_x$. ρ then gives a measure for reading resolution and is equivalent to the factor λ defined earlier for a characteristic output voltage response. Now

$$\mathbf{M}_x = -\mathbf{M}_s + 2\mathbf{M}_s x/x_1$$
$$0 \le x \le x_1 \qquad (14)$$

$$\mathbf{M}_x = -\mathbf{M}_s$$
$$x \le 0$$
$$\mathbf{M}_x = +\mathbf{M}_s$$
$$x \ge x_1 \qquad (15)$$

then

$$\partial\mathbf{M}_x(x-\bar{x})/\partial\bar{x} = -2\mathbf{M}_s(x-\bar{x})/x_1$$

for

$$0 \le (x-\bar{x}) \le x_1$$

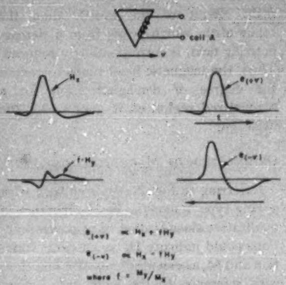

Fig. 7. Effect of oriented surface magnetization on signal

Fig. 8. Orientation of surface magnetization with direction of motion

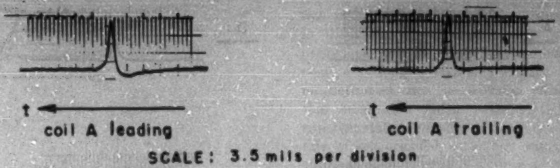

Fig. 9. Wave forms showing effect of direction of surface motion

$$\bar{x} \leq x \leq \bar{x} + x_1$$

and equals 0 otherwise.

Now substituting these conditions into equation 6, the following expression is obtained for $e(\bar{x})$

$$e(\bar{x}) \alpha \frac{\int_{\bar{x}}^{\bar{x}+x_1} \mathbf{H}_x(x)dx}{x_1} \tag{16}$$

which clearly agrees with the earlier expression in the limiting case of a step function magnetization change. The influence of x_1 on the output signal can be quickly estimated. For any value of x_1, $e(\bar{x})$ can be obtained by averaging $\mathbf{H}_x(\bar{x})$ over the interval x_1 for a set of values of $\bar{x}$. This procedure is readily done by graphical means.

The principal influence of a finite x_1 is, of course, to reduce the signal peak and increase the base line pulse width. It is evident that, for an x_1 only several times less than ρ, the approximation of the saturation change by a step function is very good. Experimental attempts to determine a magnitude for such a factor on oxide surfaces indicate that the actual situation is even more favorable to the foregoing approximation. This is in accord with earlier statements regarding the importance of the reading resolution as compared to the writing definition, because of the surface saturation characteristic, since x_1 is a measure of the latter while ρ gives a measure of the reading resolution. For a surface with a "perfect memory"

$x_1 = \rho/2$

and

$\lambda = 3\rho/2.$

Gap Size, Spacing, and Surface Thickness

The inclusion of these parameters in the theory are outlined by consideration of the following simplified head model and with the assumption of a recorded step change in longitudinal magnetization. The extension of this development to other cases is obvious and it particularly lends itself to a ready description of the manner in which gap size, spacing, and surface thickness enter into the determination of the characteristic response. Here, only $\mathbf{H}_x$ need be considered; see Fig. 5.

First neglect the surface layer depth. Then, the following expression may be written

$$\mathbf{H}_x(0) = g(\delta/\beta)\mathbf{H}_g \tag{17}$$

where $g(\delta/\beta)$ is a monotonically decreasing function and $g(0)$ is somewhat less than 1.0. The function g gives the gap fringing field attenuation. The gap size and spacing distance enter in the manner shown for this particular model for here parameter variation actually only involves scaling, a single fringing field plot sufficing. Thus, if both β and δ are changed in the same ratio, this merely amounts to a magnification or reduction of the entire field plot, and the relative field attenuation given by g would remain the same. For an actual head structure, the fringing field dependency upon these parameters can again be estimated fairly quickly by mapping. Now almost the entire magnetomotive force will appear across the gap when the reading coil is energized. Thus, $\mathbf{H}_g\beta = Ni$. Then

$$\mathbf{H}_x(0) \alpha g(\delta/\beta)/\beta \tag{18}$$

The foregoing relation indicates the dependence of the output signal amplitude, for the step function change in $\mathbf{M}_x$, upon the gap size and spacing. If both these factors are halved, then g remains the same and the relative magnitude of the peak value of the weighting function and, hence, the output signals are doubled. It is clear that for this idealized head, these reductions are equivalent to scaling the field plot by a factor of one-half in each direction and, therefore, the relative pulse width will be reduced to one-half its former value. Thus, the weighting function integral value is preserved, as would be expected from the previous discussion on this subject.

The surface thickness may be included in the following manner. Let $\mathbf{H}_x(\bar{x})$ be replaced by $\bar{\mathbf{H}}_x$, the average value of $\mathbf{H}_x$ over the surface depth. It was pointed out that the constant K in the expressions for flux is proportional to the surface thickness, for uniform magnetization throughout the surface layer, since the total magnetic field source coupling with the reading coil for any value of $\bar{x}$ is proportional to d. Likewise, K would be proportional to the head width with the 2-dimensional type of problem here. Then

$$e(0) \alpha d\bar{\mathbf{H}}_x(0) \tag{19}$$

When $\bar{\mathbf{H}}_x(0)$ is a good approximation for the average value of $\mathbf{H}_x$ over the surface layer cross section in the plane $\bar{x} = 0$, the following expression, indicating the signal amplitude dependence upon gap size, spacing, and surface thickness, may be written

$$e(0) \alpha g(\delta/\beta)d/\beta \tag{20}$$

Note that δ is measured to the center of the storage surface layer.

Vertical Probe

A vertical recording probe will be briefly considered to indicate that these concepts are not limited to any particular structure. Consider the rectangular probe shown in Fig. 6 and assume that the storage layer is on the surface of an infinite permeability undercoating. The magnetic field lines produced upon energizing a coil on the probe then have the form indicated, entering the undercoating normally which, for this case, is of infinite permeability.

Now with this form of recording, the surface will be magnetized in the vertical direction and, hence, for a step change

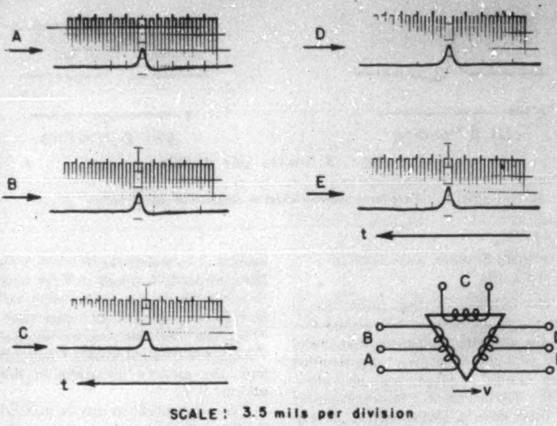

Fig. 10. Wave forms showing influence of reading coil location

in magnetization, the output signal will be proportional to the $\mathbf{H}_y$ weighting function. It is apparent here that $\mathbf{H}_y$ is symmetrical about the probe axis and, further, that $\mathbf{H}_y(\bar{x})$ will be of the same sign for all values of $\bar{x}$ near zero. These facts immediately indicate that a symmetrical output pulse having no overshoot would be expected for such a recorded step change, the return flux diffusing through a sufficiently large return path, removed from the probe region, for an actual device.

SURFACE MAGNETIC CHARACTERISTICS

Writing

The actual width of a recorded steplike change in magnetization, previously designated as x_1, is a function of the rectangularity of the saturation hysteresis loop of the magnetic storage surface material. The nonlinear saturation characteristic of the surface tends to establish a threshold writing field value which must be exceeded to alter significantly the prevailing saturation state during a reversal of magnetization. Consideration of the nature of the actual mechanism by which a small region is reversed in the environment of the opposing saturated volume would indicate a starting field greater than the coercive force by an amount related to the material magnetic properties. These facts limit the effective range of the writing fringing field, this being important on that side of the magnetic head for which the surface will not later pass through the gap region. The more rectangular the surface hysteresis characteristic the narrower will be the transition width x_1.

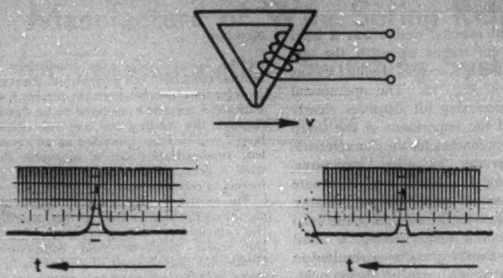
DEMAGNETIZATION

As and after a surface region is magnetized, a stable magnetic state is reached, dependent on the recorded magnetization and its self-demagnetizing field. This situation exists as long as this surface region is removed from the vicinity of the magnetic head. For a sequence of alternating steplike changes in surface magnetization, the demagnetizing field may be visualized as arising from a linear chain of opposing horizontal bar magnets the lengths of which depend on the separation existing between the step changes in magnetization.

Under equilibrium conditions, the surface magnetization will be the same after passing the magnetic head as it was prior to coming into the neighborhood of the magnetic head. However, each time a surface region passes by the magnetic head, there arises the possibility of a cyclic variation in the surface magnetic state. The line integral of the magnetic field intensity about any closed path is equal to zero in the absence of current sources. Consider a path, one branch of which extends along the surface layer center line, linking two surface points located on opposite sides of the magnetic head gap. To the extent that the presence of the magnetic head reduces the contribution to this integral along the external surface path (consider the possible choice of a path following the magnetic circuit of the head), then the other term, which arises from a demagnetizing field, is correspondingly reduced. Thus, the magnetic head tends to reduce the degree of demagnetization for a magnetized region as it goes under the head gap.

ORIENTATION OF MAGNETIZATION

Referring to Fig. 3, it is seen that with a ring-type magnetic head structure a qualitative classification of response functions could indicate $\mathbf{H}_x$ as an even function and $\mathbf{M}_y$ as essentially an odd function, with reference to the head gap. Now consider a step change in saturation magnetization where the direction of saturation is at some angle with respect to the horizontal, less than 90 degrees. Let $\mathbf{M}_x$ be the principal component, a positive step change being assumed, and first consider the case where $\mathbf{M}_y$ is also a positive step change. Now since the actual change in surface magnetization is composed of these two similar terms, the output response is the sum e_x+e_y, each term of which is proportional to its corresponding weighting function, adjusted by the actual magnitude of the associated step change in magnetization. As is clear from Fig. 7, where this composition of signals is shown, the resultant output signal, $e(+v)$ is unbalanced relative to $\mathbf{H}_x$. Now regard $e(-v)$ in Fig. 7, showing the same composition with only the sign of $\mathbf{M}_y$ changed. It is evident that this is a different characteristic output signal possessing another wave form unbalance. The base line wave form of the output signal is considerably different in these two cases. This effect is easily visualized in terms of the angular variation of $\mathbf{H}(\bar{x})$. It follows as a direct extension from the earlier theory that for an oriented step change in magnetization the output signal for each value of $\bar{x}$ is proportional to the scalar product of $\mathbf{H}(\bar{x})$ and a unit vector in the direction of $\mathbf{M}$ or, in other words, proportional to the magnitude of the component of $\mathbf{H}$ in this direction. Now regard in Fig. 4 the region giving rise to the larger $\mathbf{H}_x$ overshoot, this region being located on the coil side (right-hand side) of the magnetic head. It is seen that $\mathbf{H}$ is oriented along an axis extending into the fourth quadrant, obtained by a clockwise rotation of the horizontal axis. Then, for $\mathbf{M}$ oriented along an axis traversing the first quadrant, corresponding to the case giving rise to $e(+v)$ in which both $\mathbf{M}_x$ and $\mathbf{M}_y$ have the same sign, it is evident that the scalar product occurs between two vectors at nearly 90 degrees



SCALE: 3.5 mils per division

S-29 (30 mil radius pole tip) S-25 (2 mil radius pole tip)

Fig. 11. Effect of pole-tip radius

with respect to one another. The change in sign of $\mathbf{M}_y$, used for obtaining $e(-v)$, rotates $\mathbf{M}$ by 90 degrees and, therefore, orients it along an axis running into the fourth quadrant and much more closely parallel to the axis giving the orientation of $\mathbf{H}$ in the region of concern. Thus, it would be expected that the overshoot signal response of $e(-v)$ would be considerably more pronounced.

The significance of these two characteristic wave forms will become apparent if the writing process is briefly considered. The storage surface passes through a 2-dimensional recording field when writing. The important portion of this field, as far as writing is concerned, is the field that the surface passes through on leaving the gap region of the magnetic head. Here a surface cross section horizontally saturated in the gap itself is subject to a not inappreciable vertical magnetizing component as it passes out of the vicinity of the head. Then there will be a tendency for an orientation of the saturated surface magnetization away from the horizontal. Further, this orientation will depend on the direction of motion of the surface during writing. The two possibilities are indicated in Fig. 8. It can be seen that two characteristic output voltage wave forms might be expected, the particular one depending upon the direction of surface motion during writing, except for an entirely symmetrical recording structure. A reversal of the direction of relative motion on reading adds no additional wave forms but merely produces a mirror image of the wave form previously obtained. Fig. 9 illustrates actual characteristic read-back voltage wave forms showing the influence of the direction of surface motion. A delta-type head structure was used with a coil on one leg, as indicated in Fig. 7. The leading and trailing leg designations indicate that the coil leg is the one first passed by a surface point and vice versa respectively. Note that the type of oriented magnetization expected is in agreement with that necessary to account for these wave forms in this theory.

Theory as Applied in Design

A close interaction existed between the experimental work and the refinement and application of the theory. The concepts and relations described readily lend themselves to the interpretation of existing experimental results from which performance predictions can be made for contemplated structures. The concept of an oriented saturation magnetization was essentially developed, as outlined in the foregoing, to explain early experimental results for which an assumption of a longitudinal step change in magnetization was inadequate. While this orientation factor could not be experimentally determined, this hypothesis of an oriented saturation magnetization led to a definite pattern of behavior which could be examined. All the tests indicated consistent agreement with this picture. The procedure for head design was to use only the step function response for evaluation. Final tests were carried out with several structures with the use of recording circuitry and the magnetic head performances under operational conditions correlated excellently with the step function response results.

On the basis of the proportionality between the output signal and the weighting functions $\mathbf{H}_x$ and $\mathbf{H}_y$, the importance of reading coil location and pole-tip shape is readily apparent. Further, with oriented magnetization, even with a symmetrical core structure, the leg upon which a reading coil may be wound is of paramount importance. The prior discussion and Fig. 7 indicate that a favorable location for a leg-mounted reading coil would be the trailing leg with respect to the surface motion since an overshoot compensation is possible.

This design theory indicates quite obviously the desirability of reducing gap size, spacing between head and surface, and surface thickness from the point of view of resolution. In the experimental results presented, these parameters were fixed and, hence, these results show an optimization within this framework.

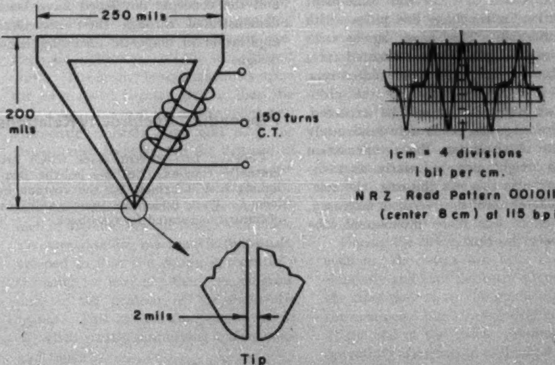


Fig. 12. Selected design and read-back pattern obtained

Experimental Results

The following wave forms were obtained in the course of the head design program for the International Business Machines *350* magnetic-disk project. Some results are from structures constructed primarily to test the usefulness of the conceptual approach described here. Some results then merely illustrate certain points. Following these, the selected head design and its performance will be indicated.

Fig. 10 shows a delta-type head and the signals obtained on read-back from coils located at various positions around the delta for the same step function change in saturation. The relative influence of coil position on overshoot can be noted. An indication of the compensation effect for the trailing leg coil position on overshoot may be seen. The leading and trailing leg identifications apply to the head orientation with respect to surface motion during writing. The signals obtained when a completely different ring-type head structure was used for writing with, however, the same gap size indicated that the recorded magnetization is primarily dependent on the gap field and not greatly influenced by pole piece shape.

Fig. 11 shows the characteristic output signal for two delta structures, both with the favorable trailing leg coil location but one (*S-25*) possessing a pointed-type pole-piece design compared to the other (*S-29*) of which the pole-tip edges adjacent to the surface, are withdrawn much more gradually. The compensation of overshoot is such that, in so far as overshoot is concerned, the responses are nearly equivalent. However, the greatly increased pulse steepness in base line approach of *S-25* and consequent reduction in the base line pulse width is noticeable. This result agrees with that expected from the estimated form of $\mathbf{H}_x$. In one sense this pointed-type head is a tailored design for the problem at hand. As would be expected, if these magnetic heads were deliberately spaced much closer, the compensation action might not be nearly as satisfactory. As this was the case, the relative magnitude of the overshoot increased. This effect was more pronounced, the narrower the tips.

DESIGN RESULTS

The final selected design was a head with a 2-mil radius tip with the coil assembly located on the trailing leg, as indicated in Fig. 12. The operational tests at increasing bit densities clearly established the importance of the sharp base line approaches for the characteristic pulse response, as other structures, while lacking this feature, did eliminate the overshoot as well. The performance of this head under the nominal operational conditions of a 1-mil spacing, a 2-mil gap, and a 1-mil surface layer resulted in a conservative estimate of about a 13-mil base line pulse width for the characteristic response and a peak-signal-to-peak-overshoot ratio of greater than 20. Nominally, no pattern modulation or read-back amplitude attenuation, would be expected below 150 bpi (bits per inch) storage density. Fig. 12 shows a pattern read-back at 115 bpi, a figure which represented an equipment limitation at the time. The specified maximum operating density was 100 bpi.

Conclusions

A theory of magnetic data recording has been presented and developed which is ideally suited to this type of recording. Qualitative principles are made available as guides for design and allow a direct approach to the evaluation of structures and the interpretation of experimental results. Further, these methods can be usefully applied from crude estimates to any desired degree of refinement, and they lend themselves directly to a study of recording structures of a more radical nature. The theory gives considerable insight into the subject of magnetic data recording. The value of this theory and the concepts developed have been demonstrated through their successful application in magnetic recording head design.

Appendix. Reciprocity Relations

Consider two current loops which are mutually coupled. Let ϕ_{ij} be the flux-linking loop i caused by the current in loop j. Then, under the same conditions of linearity as stated for read-back

$$\phi_{12} = L_{12} i_2$$

and

$$\phi_{21} = L_{21} i_1$$

where $L_{21} = L_{12}$. L_{12}, the coefficient of mutual induction, is a geometrical constant. Now for the objectives here, the current i_1 will indicate a current considered to be flowing through the reading coil and the current loop 2 will be later identified as an equivalent representation for a magnetic shell with a permanent magnetic moment, the foregoing relations applying for either case.

The most convenient way to develop the equations for the reading coil flux, based on the principle of reciprocity, is to consider the scalar magnetic field components. Hence, the justification of equations 2, 3, and 4 will be demonstrated by considering the reading coil flux contribution ϕ_{hx} which arises from the horizontal magnetization component $\mathbf{M}_x$ of the surface layer. It will be assumed that no functions vary over the surface layer depth.

Again let $\mathbf{H}_x(\bar{x})$ be the x-directed magnetic field intensity set up along the surface by a unit current through the reading coil. Then, a current i_1 energizing the reading coil will establish at the surface a magnetic field intensity proportional to $\mathbf{H}_x i_1$. The flux traversing a track cross section located at the position $\bar{x}$ with respect to the magnetic head is then proportional to $A\mathbf{H}_x i_1$, where A is the cross-sectional area of the track. L_{12} is thus seen to be proportional to $A\mathbf{H}_x$, according to the previous relation. For a current loop of differential width encircling this cross section and carrying a current i_2, it is immediately evident that the flux linking the reading coil caused by this current can be expressed as follows

$$d\phi_{12} \propto A\mathbf{H}_x i_2$$

Now this current loop can be replaced by an equivalent magnetic shell with a magnetic moment $\mathbf{M}_x$ proportional to Ai_2. Thus, because of this magnetic shell, the reading coil flux which, as it arises from $\mathbf{M}_x$, will now be designated as ϕ_{hx} can be expressed in the following manner

$$d\phi_{hx} \propto \mathbf{M}_x\mathbf{H}_x$$

The surface layer is actually composed of a continuous distribution of magnetization and, thus, the total flux ϕ_{hx} is given by the integral shown in equation 3.

Manufacture of Wire Spring Relays for Communication Switching Systems

JAMES W. RICE
NONMEMBER AIEE

FROM THE standpoint of design objectives, features, and operating characteristics, the Bell Telephone System's new wire spring relay for telephone switching systems has been described in a previous paper.[1]

Millions of these relays, Fig. 1, are now being produced annually at the Western Electric Company's Hawthorne plant in Chicago. To manufacture them in this quantity and at low cost, has required the development of machines and techniques which were unknown a few years ago. A description of some of these manufacturing facilities and their operation is the subject of this paper.

As the name suggests, one of the principal features of the design is the use of round wires rather than flat strips to make up the contact spring arrangement. These wires are molded in phenolic plastic blocks which hold the wires in permanent alignment, insulate them from each other, and which are specially shaped to facilitate their assembly into relays. In general, each relay uses three of these molded wire subassemblies. The manufacturing processes and equipment developed for their mass production will be described.

Only two basic types of wire spring assemblies are required, Fig. 2, but both are made in a wide variety of patterns to meet many different circuit requirements. One type, the "twin" wire block, is made up of movable wires arranged in pairs, and may be used for either "make" or "break" contacts depending on the position in which it is assembled in the relay and the way the terminal ends are formed. These twin wire assemblies consist of a maximum of twelve pairs of round wires held in place in a molded phenolic plastic section near one end, and with contacts welded to the other. The assemblies differ in the number of contacts needed for the particular application of the relay, and in the position of the wire pairs across the width of the molded section. In the assembled relay, one of these twin wire blocks is mounted on each side of a stationary "single" wire block, the other basic type of assembly. This type consists of 12 relatively heavy wires, also molded permanently into plastic sections, but with different types and different numbers of contacts welded to the ends of the wires.

To obtain the wide range of combinations required, including make, break, sequence, and nonsequence contacts in various positions, it is necessary to have complete flexibility in machines and tools with arrangement for quick changeover from one contact pattern to another. Also, dimensional tolerances must be closely controlled to maintain the required closure intervals, operating speed, etc.

Wire Straightening

The first step in making these wire spring subassemblies is the accurate straightening of continuous lengths of wire. Special automatic multiple-head straightening machines have been developed at Western Electric for this purpose. These machines are used directly in conjunction with hydraulic molding presses, Fig. 3, where the plastic sections are molded around the straightened wires. The straightening machines operate at a speed slightly greater than the wire consumption of the molding dies, and automatic controls start and stop the straightener according to the demand at the press. Two sizes of nickel-silver hard-temper wire are used; 0.0226 inch in diameter for the twin wire blocks and 0.040 inch in diameter for the single-wire block. The straightening machines have been developed so that the design is essentially the same for wire of either size, differing only in the contour of the removable blades. This assures flexibility in setup as well as greatly simplifying maintenance and repair.

A separate spool of wire is provided for each wire required in a molded block. A capstan with individual pulley adjustment for each wire pulls the wire from the supply spools and guides it between drive rolls which push the wires through tubes to rotating straightening heads; see Fig. 4. The straightening heads are tubular and are separated in the middle so that each half can be rotated in opposite directions. Inside the head and rotating with it is a removable spindle with a free coupled joint in the middle; see Fig. 5. Held in each half of the spindle is a pair of precisely contoured die blades, which flex the wire and burnish the surface as they rotate around the wire. Halfway through the head the direction of rotation is reversed, so that the wire emerges without torsional stress, but with sufficient longitudinal surface stress to resist bending. The absence of torsional stress is of equal importance with straightness, the reason for which will be discussed later.

Automatic Molding

The wire blocks are molded in progressive dies, Fig. 6, four at a time, on two parallel arrays of either 12 or 24 wires. When making the 12-wire single block, half the wires from a 24-head straightener are guided into each forward cavity. When the 24-wire twin blocks are being made, the entire production of a 24-head straightener is guided into each forward cavity, and two machines are set up at each molding press.

The first station of the progressive molding die serrates or flattens a small section of the wires to provide a means of anchoring them in the plastic. Phenolic preforms, previously briquetted from powder in a mechanical tabletting press, are electronically preheated and automatically fed into the die beneath a transfer ram at the second station, where the actual molding is done. After the plastic is sufficiently cured under heat and pressure, the die opens and the cluster of four blocks is ejected from the mold and indexed to the third station where the blocks are clamped between water-cooled plates and the center cull sheared out. The fourth and final operation in the molding cycle is shearing the wires between the molded sections to form individual wire blocks.

During the entire series of molding operations, the wires are held taut continuously and kept perfectly aligned from the time they enter the guide slots until the completed blocks are finally cut apart at the end of the series. Ordinarily, no operator's attention to individual wires is necessary until one of the spools is empty.

Paper 56-650, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 23, 1956; made available for printing April 19, 1956.

JAMES W. RICE is with the Western Electric Company, Inc., Chicago, Ill.

Credit is due the many people who assisted individually in this development. Engineers at both the Western Electric Company and the Bell Telephone Laboratories co-operated fully and important contributions were made by both organizations.

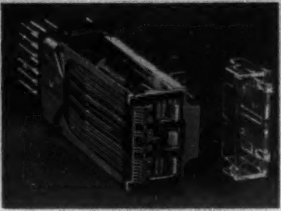

Fig. 1. **Wire spring relay, with contact cover removed**

At that time, the wire straightener is rolled away and the wires from a refilled straightener are threaded through the machine.

Press Controls

The electric controls for all the press operations are housed in a cabinet adjacent to the molding machine. The operation of the hydraulic press rams, the electronic preform heater, the feed mechanism, and the pneumatic devices on the die are all precisely timed and perfectly co-ordinated. Any operational sequence or length of cycle can be established for repetitive manufacture. On the other hand, turning a switch will place the entire operation on manual control for setup or maintenance.

Flash Removal

Even with the most careful die construction, the high molding pressure sometimes forces bits of plastic into the crack at the parting line of the die or out of the cavity along the wires. This leaves thin, brittle fins or "flash" which must be removed, lest particles break off later and lodge between the electric contacts. This flash is removed in special conveyorized grit-blasting machines; see Fig. 7. Here the blocks are loaded into fixtures, carefully designed to shield the fine molded wire guide teeth, but to expose the areas where flash is likely to occur. The blocks are then carried past nozzles where compressed air laden with ground walnut shells blasts the flash away. As the blocks are removed, they are placed in special slotted magazines, and not handled individually beyond this point.

Automatic Transfer Lines

The second major sequence of operations in the manufacture of these wire spring relay parts is perhaps more impressive than the wire-straightening, molding and flash removal just described. These are the remainder of the operations on the molded wire blocks which transform them into complete subassemblies, ready for final assembly into the relays.

Forming the contact end of the wires, cleaning, welding contacts in any pattern, coining the contacts to close tolerance, twisting and forming the terminals, clipping to exact length, tension-bending the wires, and removing unused wires are all done in integrated lines of machines through which the parts are transferred and processed completely automatically; see Fig. 8. As the parts come from the molding room they are stacked in a 6-position loading turret, at the left-hand end of the line. A shuttle-type transfer rail extending the length of the machine pulls out the bottom block onto the transfer track, leaves it in position and returns for the next part. Removal of the last block in the stack signals the turret to index to the next position.

At this time, perhaps some of the critical dimensions of the relay should be reviewed. These dimensions, as well as the way the parts fit together in the final assembly, govern the way the wire blocks are located at the work stations in the automatic line. In the assembled relay, the single-wire block is located between the two twin wire blocks, and pairs of precision dowels, molded as part of the plastic block, pass through mating holes in the twin wire blocks. This means of permanent and precise alignment is an important feature of the design for rapid assembly. All of the critical dimensions on the wire blocks are measured from the dowels or holes. At each work station in the transfer lines, the centers are first found and then the operations performed with constant dimensional relationship to them.

The first unit in the line twists the two wires of each pair together at the terminal side of the plastic block, which is an important operation in making the relay terminals suitable for solderless wrapped connections. This is actually a double unit and occupies two transfer track positions. Two identical heads with six spindles each twist alternate pairs of wires on two wire blocks with each operating cycle.

The second work station is a 35-ton press which coins the 12 twisted pairs into a trapezoidal cross section, see Fig. 9. This completes the solderless connection feature of the terminal and the two round wires are now joined into a rigid structure having the necessary sharp edges.

The third machine unit in the automatic line is a 8-ton hydraulic press equipped with a 2-stage progressive tool. Here is performed the most complex wire-forming operation in the entire line.

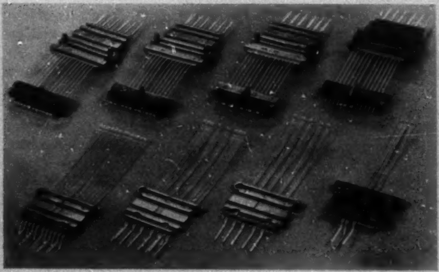

Fig. 2. **The two types of wire spring assemblies, showing various contact combinations**

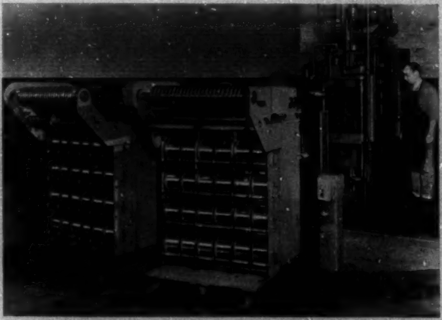

Fig. 3. **Wire straightening machines in conjunction with plastic molding press**

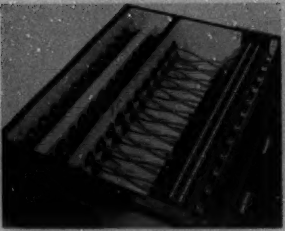

Fig. 4. Interior of 24-head wire straightening machine

Fig. 5. (right). Double spindle showing complement of two sets of removable die blades

The contact ends of the wires must be sharply offset to provide room for the actuating card immediately behind the contacts. The operation gives the wires a double reverse bend similar to the letter Z and at the same time the very tips of the wires are flattened and slightly curved on one side to form the base for the contact, and flattened to a plane on the opposite side to make a low resistance surface for the contact-welding operation. Also in this operation, the wires are flattened and slightly curved for a short distance immediately back of the offset bend where the actuating card will bear upon the wires. A sketch of this important wire shape is shown in Fig. 10. All of these dimensions must be held to close tolerances since they directly affect the contact-operate points. Here also is where the need for stress-free and nearly perfectly round wires becomes apparent. Release of stresses or rolling of the wires as the forming and flattening pressure is applied, will cause intolerable mislocation of the contacts. Fig. 11 shows the contact end of a relay having one twin wire block with torsionally stressed wires and the other without. The second station in the 2-stage tool clips the contact ends of the wires precisely and evenly.

A cleaning station is next in line, where a stream of liquid trichloroethylene washes all traces of dirt and oil off the wire ends where the precious-metal contacts are to be welded. At another station, also under the exhaust hood, a stream of compressed air dries the wires.

Twin Wire Contact Welding

The automatic twin wire contact-welding machine is the large unit near the middle of the line. Here a bit of previous metal is welded to the tip of each wire which, along with another precious-metal contact on the mating single wire, makes up the pair of surfaces which opens or closes the electric circuit when the relay operates. The contact material is palladium, 0.009 inch in thickness, with a 0.001-inch-thick layer of 22-carat gold fused to the top surface. This bimetal tape is about 0.030 inch in width and is fed to the machine in long lengths, wound on individual reels. On the bottom surface is a small bead, or ridge, which constitutes the "projection" for the welding process.

The wire blocks are transferred into the machine from the left side and precisely located with the reference holes in the plastic block engaged on pilot pins. The welding "head" itself consists of 12 electrodes, one for each alternate wire of the 24-wire block. An identical head is located farther along where contacts are welded on the even-numbered wires. As the block is positioned with the reference holes in the plastic engaged on pilot pins, a guide comb engages the individual wires near the plastic block, and then moves toward the ends of the wires, spacing and positioning them precisely along the top of the common lower electrode. Drive rolls feed the individual contact tapes forward the required distance (0.050 inch), and positions the ends over their respective wires. Cantilever suspended individual electrodes descend and press the tape ends firmly against the flattened surfaces of the wires, and the welds are made. The tapes are then clipped, and the part transferred to the second welding head where the process is repeated for the odd-numbered wires.

As was mentioned earlier, if the particular part being made will not require contacts in some positions, they will not be welded, and no precious metal will be wasted. The welding machine is completely versatile in this respect, since all 24 circuits are completely independent and the desired pattern is preset with the bank of toggle switches near the left side of the control panel, above the machine. The mechanical movements necessary to transfer and locate the part, operate the electrodes, feed, clamp, and clip the tape, all are controlled by a master cam shaft and thus kept in precise timing throughout the cycle.

The next operation on the twin wire block is the heaviest and also the most critical of the series. This is performed on a 15-ton press with a single station tool, so that the work station is directly under the ram, and distortion is minimized. This operation "builds in" the critical contact location dimension by coining the contact so that it has a smooth, curved surface, at the same time reflattening the card-bearing surface above the contacts.

The next operations are performed in an 8-ton press with a 2-station progressive tool. Here the terminal end of the blocks is completed by offsetting the wire pairs into staggered rows for easier wiring, and clipping the ends evenly. The last press is also 8-ton with a 2-station tool. The first station forms an offset bend in each wire so that the relay contacts will press against each other with the required force. The second station of this tool clips off any wires which are not to be used for the particular code of relay being run. This tool has a series of twelve clipping details which can be quickly arranged to clip or not clip in any pattern.

From this station the parts are carried to the end of the transfer track to the machine-unloading station where they are stacked in holding magazines. This station, like the loading station at the head end of the line, is also built on a turret but has eight stations instead of six. As each magazine is filled, the turret indexes, and brings an empty magazine into position. When six or seven magazines are

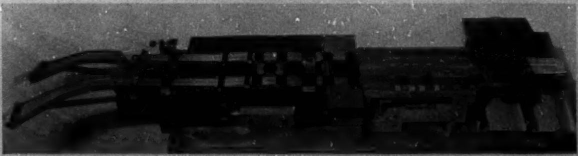

Fig. 6. Lower half of 4-cavity progressive molding die

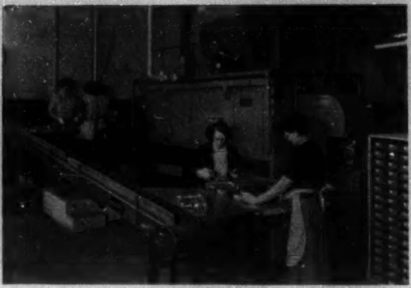

Fig. 7. Conveyorized grit-blasting machine for removal of molding flash

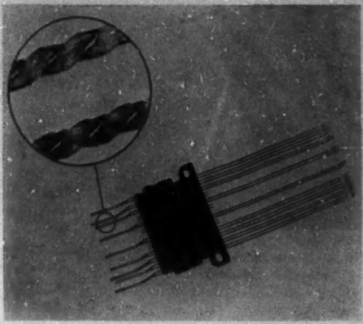

Fig. 9. Twin wire terminals twisted and coined for solderless wrapped connections

filled, the operator removes them and attaches empty magazines to the turret.

The control center is located above the welder, near the middle of the line. Here are located start and stop switches for each of the machine units as well as pilot alarms to show the location of any trouble condition. A relay cabinet is located farther down the line at the rear. The circuit is so designed that all the machines are electrically interlocked to keep them perfectly timed and to assure that all have completed their cycles before the succeeding cycle begins.

Tools and Presses

Several unique features have been incorporated into the designs of the press tools. With the reciprocating transfer method of feeding, the alignment of the transfer track with adjacent units is quite important. Each press tool is designed on the double-die set principle: a die set within a die set. The outer die set locates and supports the section of transfer track through the tool and is installed permanently in the press. The inner die set carries the intricate forming or cutting details and is mounted with precision screw dowels within the outer set. With this arrangement, the inner set can be quickly removed for maintenance, and replaced without disturbing the critical alignment, thus causing minimum down time for the line.

The double-die set principle and the general massiveness of the tool structure is also an important consideration in reducing distortion under pressing pressure. Any slight distortion is particularly objectionable when the operation is primarily one of squeezing to shape, as many of them are.

These operations of squeezing the wires to close tolerances also led to the selection of hydraulic presses rather than any type of crank press. Heavy stop blocks which locate the bottom of the stroke are designed into each press tool. The stops are ground to proper dimension in the tool room and any tool can be installed without adjustment of the press stroke.

Single-Wire Lines

Similar automatic transfer machinery and tooling for the final operations on the single-wire block has been developed and is in operation. Here also the blocks are handled in magazines from which they are mechanically unloaded, and transferred through the operations of precision clipping, contact welding, contact sizing, terminal forming, and tension bending, finally to be reloaded into magazines. The actual operations and tooling for the single blocks are, except for the contact welding, generally less complex than those for the twin wire blocks.

The only forming operations are those of serrating and offsetting the terminals and tension bending. Since the wires are heavier, individual rather than paired, and held in plastic at both ends, there is no problem of individually locating and guiding the wires at the work stations. The contact-welding machine, however, is altogether different from the twin wire contact welder.

Percussion Welding

The contacts on the single wire blocks are made up of small rectangular blocks of cupro-nickel with a 0.010-inch layer of palladium on one or both sides. These contact blocks are welded to the tips of the wires in various combinations; see Fig. 2. The design of the wire block is such that clamp electrodes, normally used in resistance welding and located near the weld zone, could not be used. A little-used welding technique, percussion welding, was developed for this application.

Simply stated, percussion welding involves the application of a high potential, 900 to 1,800 volts, across a gap between the parts as they move toward each other. The resulting arc heats the abutting surfaces before they meet, so that a thin layer of metal on each surface is brought to welding temperature, and

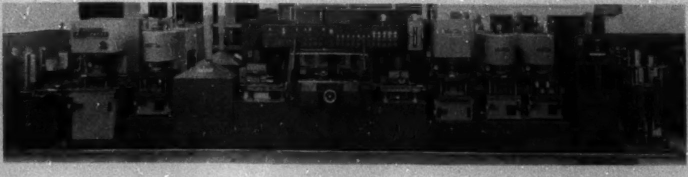

Fig. 8. Automatic transfer machine for contact-welding and wire-forming of twin wire blocks

Vol. 7
Pt. 1
1956

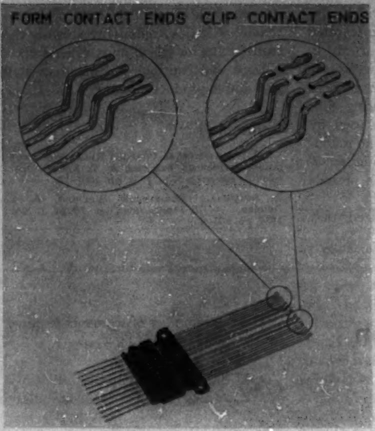

Fig. 10 (left). Sketch of formed and flattened end of twin wires before welding of contacts

Fig. 11 (above). Misalignment of relay contacts caused by torsional stresses or oval wires

the welding is made as the parts come together with an impact.

These are four contact conditions that may be applied to any of the 12 wires of the single-wire block; see Fig. 12. For a break relay contact, the palladium cap on the contact is on the bottom, and for a make contact, the cap is on the top. For transfer or sequence contacts, a palladium cap is required on both upper and lower sides. For relays requiring less than twelve contacts, some wires have the contact block omitted entirely. Three tapes, with palladium caps on the top side, the bottom side, and both sides, are fed from each side of the machine to two welding heads. The welder selects the type of contact needed, cuts it from the proper tape, and welds it to the proper wire. This information is preset by the setup man who has only to press one of four colored buttons associated with each of the 12 wire positions.

In operation, two wire blocks at a time are carried into position by the reciprocating transfer bar, located and clamped in a movable nest. During this process, the tape selector on each side of the machine has found the proper tape and has pushed it into a clipping die. Two punches move forward, clip contacts from the tapes, and carry them to transfer fingers which push them away from the punch and into movable jaws. The jaws are held on spring-propelled carriages, facing the first wire on each of the two nested wire blocks. One terminal of a charged capacitor is connected to the outside end of the wire through a movable brush and the other terminal to the jaw carriage through a flexible lead. At the proper instant, a cam releases the carriage which propels the jaw and contact toward the wire end. As the gap decreases, the arc establishes itself and heats the two abutting surfaces. As the surfaces meet, the arc is extinguished and the molten metal fuses. The jaw is pulled off the contact and returns to the loading position for the next contact while the wire blocks are indexed to the next wire position, where the process is repeated.

The wire blocks are handled two at a time and the two welding circuits are separate and independent. The capacitors are charged during the time the jaws are returning for their next contacts and the blocks are being indexed to the next wire position.

As stated earlier, and as shown in Fig. 2, some blocks do not require contacts in every position. The first percussion welders took care of this by not feeding the tape and cutting off the high voltage at these positions, but otherwise completing the entire mechanical cycle once for each of the 12 wires. A machine of a later model is now completed, which carries the blocks directly over the unused wire positions, stopping for the welding cycle only where a contact is required. This, of course, enables a marked increase in output, especially for those codes requiring only two or three contacts. This feature is completely automatic and any contact pattern may be obtained by depressing the proper buttons on the code selection panel.

The percussion welding machine of an earlier model has been described in a previous paper,[2] along with a discussion of many of the problems associated with the development of this unique welding process.

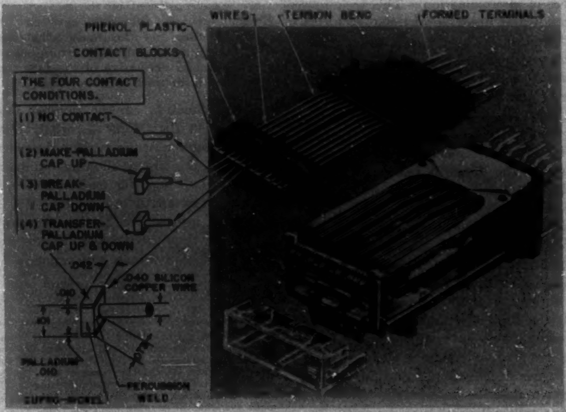

Fig. 12. Single-wire block with percussion-welded contacts. Also view of wire spring relay

Summary

This paper has described the manufacture of the major subassemblies for the general-purpose wire spring relay. Their mass production to close tolerances and at low cost has required the development of entirely new and different machines and techniques. Several machines of the type discussed are already in operation and more are under construction to satisfy an ever-increasing demand.

The combination of such widely different kinds of processes into integrated machine units is a great step forward in the march toward the automatic factory so widely acclaimed in these modern times. Knowledge gained during this development has already been used by Western Electric in planning the manufacture of future communication apparatus and in lowering the cost of present Bell System products.

It will doubtless be recognized that automatic facilities of the type described require a major capital investment, the justification for which must depend upon a large and continuing demand as well as a stable product design.

Optimum Linear-Segment Function Generation

HOWARD HAMER
ASSOCIATE MEMBER AIEE

DURING the past few years, the accuracy of linear analogue-computing components has been improved to the extent that the present limitation on solution accuracy in analogue computation and simulation is caused almost entirely by the errors in nonlinear equipment. One nonlinear device which has found extensive use is the diode-type generator for arbitrary functions. In general, this device approximates a given function by means of short linear segments, which are located in the function plane as closely as possible to the desired function to obtain a minimum error of approximation. This technique is known as linear approximation.

Fig. 1 shows a typical linear approximation to an arbitrary function. The point at which one straight-line segment meets the following segment is known as the break point for the succeeding segment. If both the slope and break point for each segment are continuously variable, the device is known as a variable-base function generator. As can be seen from Fig. 1, there are an infinite number of adjustments possible for such a generator, each of which approximates the function to some degree. Only one of these, however, is optimum in the sense that the maximum error between the given function and the approximation is as small as possible for the given function and a given number of segments. It is the purpose of this paper to describe an analytic technique which makes it possible to determine the smallest error obtainable and the break points and slopes which will achieve the optimum approximation.

Mathematical Development

In the Appendix it is shown that, if a section of a curve $y = f(x)$ is approximated by a straight-line segment (see Fig. 2)

$$(\Delta x)^2 = \frac{8E}{|y''|} \tag{1}$$

where

(Δx) = the length of the straight-line segment projected on the x-axis
E = the greatest difference between the function and the straight-line segment, and is called the error
y'' = the second derivative of the function, and is assumed constant over (Δx)

If the function can be divided into regions such that y'' is essentially constant throughout each region, then, for a given E, the largest allowable value of (Δx) can be found for each region. If a region is of length C_kX_m, where X_m is the total interval of the independent variable x, then the number of segments required to approximate this region is

$$N_k = \frac{C_kX_m}{(\Delta x)_k} \tag{2}$$

The total number of segments required for the entire curve is

$$N_t = \sum_{k=1}^{n} \frac{C_kX_m}{(\Delta x)_k} \tag{3}$$

If all the regions are of equal length, then C_k is a constant, equal to $1/n$, so that

$$N_t = \frac{X_m}{n}\sum_{k=1}^{n} \frac{1}{(\Delta x)_k} \tag{4}$$

If the end points and mid-point of a region are x_ky_k, $x_{k+1}y_{k+1}$, $x_{k+2}y_{k+2}$, then $x_{k+2} - x_k = X_m/n$ and

$$y'' \cong \frac{y_k + y_{k+2} - 2y_{k+1}}{(x_{k+1} - x_k)^2} \tag{5}$$

Since $x_{k+1} - x_k = {}^1/_2\,(x_{k+2} - x_k)$

$$y'' \cong \frac{4n^2(y_k + y_{k+2} - 2y_{k+1})}{X_m{}^2} \tag{6}$$

Let $y_{k+1} = y_k + \Delta_k{}^1$, $y_{k+2} = y_{k+1} + \Delta_{k+1}{}^1 = y_k + \Delta_k{}^1 + \Delta_{k+1}{}^1$. Then

$$y_k + y_{k+2} - 2y_{k+1} = \Delta_{k+1}{}^1 - \Delta_k{}^1 = \Delta_k{}^2 \tag{7}$$

where

$\Delta_k{}^1$ = the first difference of the k^th^ region
$\Delta_k{}^2$ = the second difference of the k^th^ region

In general

$$y_k + y_{k+2} - 2y_{k+1} \triangleq \Delta_k{}^2 \tag{8}$$

Thus

$$y'' \cong \frac{4n^2\Delta_k{}^2}{X_m{}^2} \tag{9}$$

or

$$(\Delta x)_k{}^2 = \frac{8EX_m{}^2}{4_n{}^2|\Delta_k{}^2|} \tag{10}$$

$$\frac{1}{(\Delta x)_k{}^2} = \frac{n^2|\Delta_k{}^2|}{2EX_m{}^2} \tag{11}$$

$$\frac{1}{(\Delta x)_k} = \frac{2n\sqrt{|\Delta_k{}^2|}}{\sqrt{8EX_m}} \tag{12}$$

HOWARD HAMER is with Electronic Associates, Long Branch, N. J.

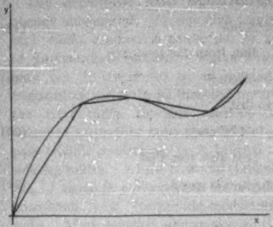

Fig. 1. A typical linear approximation

$$(\Delta x)_k^2 = \frac{2E(x_{k+2}-x_k)^2}{y_k+y_{k+2}-2y_{k+1}} \tag{12A}$$

Substituting equations 12 and 12(A) in equation 4

$$N_t = \frac{X_m}{n}\sum_{k=1}^{n}\frac{2n\sqrt{|\Delta_k^2|}}{\sqrt{8E}\,X_m}$$

$$= \frac{1}{\sqrt{2E}}\sum_{k=1}^{n}\sqrt{|\Delta_k^2|} \tag{13}$$

Solving for EN^2

$$EN^2 = \frac{1}{2}\left(\sum_{k=1}^{n}\sqrt{|\Delta_k^2|}\right)^2 \tag{14}$$

which is the equation relating error and number of segments for the optimum linear approximation to an arbitrary function.

Applications

Equation 14 can be used to find the approximation error if the number of segments is given, or to find the number of segments required for a desired accuracy. The total range of the independent variable x is divided into n intervals, where n is arbitrary, but should be as large as calculation time permits. The function is tabulated at the end points of these intervals and also at the mid-points. Table I is a tabulation for $y = \epsilon^{-x}$ for which 10 intervals are used. The second differences are computed for these 10 points, the square roots taken and summed. When this number is put into equation 14

$$EN^2 = 1/2(0.3934)^2 = 0.0774$$

If it is desired to approximate this function with five segments

$$E = 1/25 \times 0.0774 = 0.0031 \text{ or } 0.31 \text{ per cent}$$

If, however, an accuracy of only 1.0 per cent is required, with the use of a minimum number of segments, e.g., a special loaded potentiometer, perhaps, where segments cost money

$$N = \sqrt{\frac{0.0774}{0.01}} = 2.8$$

This analysis makes no provision for the technique known as error-splitting, whereby the approximating linear segment is moved vertically by half the error and results in a final error which is half, approximately, of that calculated by equation 14. If this technique is to be used, and it is almost always advisable, the value for E in equation 3 must be twice the final desired or expected error.

Once equation 14 has been used, and N and E are determined, equation 12(A) can be used to locate the required end points for the optimum approximation. A point x_1 is chosen which is about where the first segment is expected to end. This defines a region

$$x_0 \leq x \leq x_1$$

Equation 12(A) is applied to this region, yielding $(\Delta x)_1$, which is the length of the first interval. A second region

$$x_0 + u_1 \leq x \leq x_2$$

is then chosen, equation 12(A) applies, and $(\Delta x)_2$ is found, which defines interval 2 as

$$x_0 + u_1 \leq x \leq x_0 + u_1 + u_2$$

This process is repeated until the range of the independent variable is exhausted. The total number of segments required should be the same as that used in, or obtained from, equation 14. Once the segment lengths have been determined it is a simple matter to set up the approximating function.

Example: $y = \epsilon^{-x}$ in 5 segments.

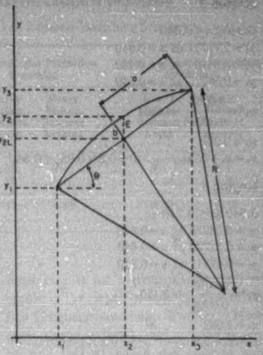

Fig. 2. Linear approximation to a short segment of curve

From Table I

$$\sum_{k=1}^{10}\sqrt{|\Delta_k^2|} = 0.3934$$

Step 1

From equation 14

$$EN^2 = \frac{(0.3934)^2}{2} = 0.0774$$

If $N = 5$

$$E = \frac{0.0774}{25} = 0.0031$$

With error-splitting

$E_s = 0.00155$ or 0.155 per cent

Step 2

Estimate region 1 from $x = 0$ to $x = 0.2$

$$u_1^2 \triangleq \frac{(\Delta x)^2}{(x_3-x_1)^2} = \frac{2E}{y_1+y_3-2y_2}$$

from equation 12A.

$y_1 = 1.00000$ at $x = 0$
$y_2 = 0.90484$ at $x = 0.1$
$y_3 = 0.81873$ at $x = 0.2$

$$u_1^2 = \frac{0.0062}{0.00905} = 0.685$$

$u_1 = \sqrt{0.685} = 0.828$
$x_1 = 0.828 \times 0.2 = 0.166$
Use $x_1 = 0.160$.

Region 2

$0.160 \leq x \leq 0.360$
$y_1 = 0.85214$ at $x = 0.16$
$y_2 = 0.77105$ at $x = 0.26$
$y_3 = 0.69768$ at $x = 0.36$

$$u_2^2 = \frac{0.0062}{0.00772} = 0.803$$

$u_2 = 0.896$
$x_2 = x_1 + 0.2u_{n1} = 0.16 + 0.2 \times 0.896 \cong 0.340$

Region 3

$0.340 \leq x \leq 0.540$
$y_1 = 0.71777$ at $x = 0.340$
$y_2 = 0.64404$ at $x = 0.440$
$y_3 = 0.58275$ at $x = 0.540$

$$u_3^2 = \frac{0.0062}{0.00644} = 0.964$$

$u_3 = 0.981$
$x_3 = x_2 + 0.2u_{n3} = 0.340 + 0.2 \times 0.981 \cong 0.540$

Region 4

$0.540 \leq x \leq 0.740$
$y_1 = 0.58275$ at $x = 0.540$
$y_2 = 0.52729$ at $x = 0.640$
$y_3 = 0.47711$ at $x = 0.740$

$$u_4^2 = \frac{0.0062}{0.00528} = 1.175$$

$u_4 = 1.082$
$x_4 = x_3 + 0.2u_{n4} = 0.540 + 0.2 \times 1.082 \cong 0.770$

Region 5

$0.770 \leq x \leq 0.970$
$y_1 = 0.46301$ at $x = 0.770$
$y_2 = 0.41895$ at $x = 0.870$
$y_3 = 0.37908$ at $x = 0.970$

$$u_5^2 = \frac{0.0062}{0.00419} = 1.48$$

$u_5 = 1.22$
$x_5 = x_4 + 0.2u_{n5} = 0.770 + 0.2 \times 1.22 \cong 1.000$
$y_5 = 0.36788$

The resultant end points which will approximate $y = \epsilon^{-x}$ to 0.15 per cent from $x = 0$ to $x = 1$ are:

x	y
0	0.99845
0.160	0.85059
0.340	0.71022
0.540	0.58120
0.770	0.46146
1.000	0.36633

Appendix

In Fig. 2 a short segment of a curve is shown, together with a straight-line approximation to the curve, intersecting at end points x_1, y_1 and x_3, y_3. It is assumed that the average radius of curvature of the segment of curve is R so that the curve is very similar to an arc of a circle of radius R passing through the end points and an intermediate point x_2, y_2. The corresponding intermediate point on the linear segment is x_2, y_{2L}, and the error of approximation is $E = y_2 - y_{2L}$. The angle of slope of the linear segment is θ and, if the preceding assumptions hold

$$\tan\theta \cong \left(\overline{\frac{dy}{dx}}\right) \tag{15}$$

where $(\overline{dy}/dx)$ is the average first derivative of the function over the interval. From the geometry

$$a^2 + (R-b)^2 = R^2 \tag{16}$$

or

$$a^2 + R^2 - 2Rb \cong R^2 \tag{17}$$

so that

$$a^2 \cong 2Rb \tag{18}$$

But, from the geometry

$$b = E\cos\theta \tag{19}$$

so that

$$a^2 \cong 2RE\cos\theta \tag{20}$$

It is also seen that

$$x_3 - x_1 = 2a\cos\theta \tag{21}$$

or

$$a \cong \frac{x_3 - x_1}{2\cos\theta} \cong \frac{\Delta x}{2\cos\theta} \tag{22}$$

where $\Delta x \triangleq x_3 - x_1$.
The definition of radius of curvature is

$$R \triangleq \frac{[1+(y')^2]^{3/2}}{|y''|} \tag{23}$$

where y' is the first derivative of $y = y(x)$, and y'' is the second derivative.

Since y' also equals $\tan\theta$

$$[1+(y')^2]^{1/2} = \frac{1}{\cos\theta} \tag{24}$$

$$R = \frac{1}{|y''|\cos^3\theta} \tag{25}$$

Substituting equations 22 and 25 into equation 20

$$\frac{(\Delta x)^2}{4\cos^2\theta} = \frac{2E\cos\theta}{|y''|\cos^3\theta} \tag{26}$$

$$(\Delta x)^2 = \frac{8E}{|y''|} \tag{27}$$

Automatic Protection Switching for TD-2 Radio System

G. H. KLEMM
ASSOCIATE MEMBER AIEE

Synopsis: Intercity transmission of television programs and telephone conversations is now provided via a network of *TD-2* microwave radio relay equipment operating on a transcontinental basis. Whenever service interruption threatens because of equipment troubles or atmospheric disturbances in the transmission path, a switching system automatically and quickly substitutes a stand-by wide-band microwave radio channel for the defective channel. The circuits and operation of this switching equipment are described.

TD-2 Microwave Radio Relay System

The *TD-2* radio system is designed especially for long-haul backbone-route service between major population centers, but it is also adaptable to light-route applications. Radio repeater stations are frequently located on high land and generally use towers or other high antenna supports to provide clear line-of-sight transmission paths which average approximately 30 miles between stations, depending upon the intervening terrain. The information is transmitted via very sharply focused microwave radio beams directed from one repeater station to the next.

Six 2-way broad-band radio channels are provided on a fully loaded *TD-2* system and any one channel will carry several hundred telephone circuits or one television signal. Each direction of transmission is independent of the other. The six channels for one direction of transmission use common transmitting and receiving antennas, and each channel uses independent electronic equipment. Each repeater station contains a common power plant. Batteries floating across the output of this power plant provide service in the event of short-time primary-source power failures and, in the event of long-time primary-source power failures, an engine-generator set is switched into service. The fusing and discharge leads are arranged so that single equipment failure will affect no more than one radio channel in one direction of transmission. Repeater stations are normally unattended but automatic alarms and remote controls are provided via wire lines to control centers. The latter are usually located at major population centers along the route or at other Bell Telephone System locations which are continuously manned.

Paper 56-698, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 28, 1956; made available for printing April 27, 1956.

G. H. KLEMM is with Bell Telephone Laboratories, Inc., Murray Hill, N. J.

The microwave radio signal is frequency modulated. At repeater points, each radio channel is converted to an i-f (intermediate frequency) signal which may be: 1. connected to an outgoing transmitter and antenna directed toward the next radio repeater station; 2. switched to another radio channel to bypass trouble conditions; or 3. bridged to side-leg routes. At the terminal stations, the i-f signal is converted to its original base-band a-m (amplitude-modulated) form. More detailed information on the *TD-2* system may be found elsewhere.[1,2,3]

Service Failures

Service via radio equipment may be interrupted by equipment failures or by radio fades. Some equipment troubles are relatively slow (1 or more seconds) in causing serious degradation in service, e.g., when an electron tube heater fails, while some equipment troubles may interrupt service instantaneously, as in the case of the breakdown of a capacitor or opening of a defective connection. The use of high-quality components and preventative maintenance on a routine basis reduces equipment failure to a minimum.

The atmosphere through which the sharply focused microwave radio beam propagates from one repeater to the next is a dielectric with continuously varying characteristics. The beam is often divided and travels by more than one path so that the signal seen by the receiver is a composite of many signals all of different amplitude and phase. The magnitude of the received signal is continuously varying and this condition is referred to as fading. Under extreme conditions, the fade can cause complete service failure.

The effect of a fade in the *TD-2* radio system is an increase in noise in the telephone and television circuits. A deep fade may cause the carrier-to-noise ratio at the input to a repeater to approach unity. As the fade grows still deeper, the signal-to-noise ratio will drop off still more rapidly for a given db (decibel) increase in the depth of fade because of the f-m (frequency-modulated) effect. However, this so-called breaking point is well beyond that at which the noise is considered to be intolerable. Radio systems are designed to provide transmission margin sufficient to protect against fades of moderate depth. In those cases where the fades are deep enough to cause service failure, transmission usually returns to normal in a short time.

Available studies[4] indicate that the probable duration of interruptions of service caused by equipment failures on a 4,000-mile transcontinental 1-way channel of the *TD-2* radio system is 6.65 per cent of the time or 95 minutes per day.

Vol. 7
Pt. 1
1956

A similar figure caused by fading in the worst fading period is 1.46 per cent of the time or 21 minutes per day. This latter figure is defined as the point where the noise in the top channel of a 480-channel telephone system is in excess of 40 dba (decibels adjusted) at the −9-db transmission level point. The relatively large outage time caused by equipment failures is because of the length of time required to dispatch a man to the trouble location and to repair the equipment. The outage time which is caused by fading is because of the large frequency of occurrence of the fades.

Expected Improvement of Service with Automatic Protection Switching

Welber, Evans, and Pullis[4] have shown that, if a *TD-2* route is divided into a number of switching sections, with each section containing ten repeater stations and using frequency diversity (one radio channel of the *TD-2* radio system being used as a protection channel for the five regular channels), the outage time for any of the other five regular channels caused by equipment failures will be 0.1 per cent. The outage time caused by fading will be 0.13 per cent during the summer night's heavy fading conditions. These figures include provision for the probable outage time for the protection radio channel.

Table I summarizes the probable outages caused by equipment failures and fading with and without automatic switching.

Automatic Protection Switching

When automatic protection switching is used with the *TD-2* radio system, normal service is provided on one to five regular radio channels and one channel, called the protection channel, is held in reserve and is automatically substituted for any one of the five regular channels during trouble conditions.

SWITCHING SECTION

The probability of failure of any radio channel increases directly with the number of repeater sections in tandem.[4] Since the protection channel is subject to the same hazards as the regular channels, if the number of repeater stations between switching points is limited, 1. the protection channels will be available for service a greater proportion of the time and 2. the regular channels will require the protection channel services for a smaller proportion of the time. Thus, by dividing the *TD-2* route into a number of switching sections, the reliability of a long route will be increased. An economic balance between the cost of the automatic protection switching and the desired degree of reliability determines the number of repeaters in a switching section. In practice, this figure is in a range from 5 to 15 repeaters per switching section.

CIRCUITS AND EQUIPMENT OF A SWITCHING SECTION

Each switching section is an independent unit within which all the functions of automatic protection switching are performed, but alarm leads and manual control leads may be connected to remote-control centers. As in the case of the basic *TD-2* radio system, the switching equipment for each direction of transmission is independent of that used in another direction of transmission. Each switching section requires:

1. Monitoring and evaluating circuits at the receiving end of the switching section.
2. Control circuits at both ends of the switching section.
3. Switching equipment at both ends of the switching section.
4. A high-speed wire-line facility (voice circuit) transmitting from the receiving to the transmitting end of the switching section.

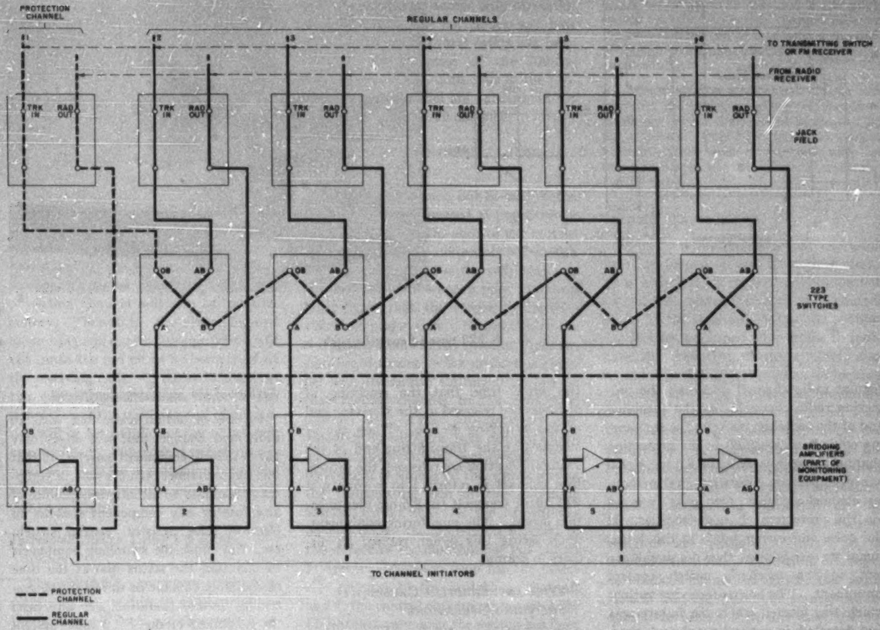

Fig. 3. TD-2 auto-switching receiving switch

Fig. 1 shows how the equipment is interconnected. All switching and monitoring is done at the 70-mc (megacycle) i-f. The function of the monitoring and evaluating circuits is to monitor each radio channel at the receiving end of the switching section and to call for the protection channel to be bridged into service or to be released from service, as the conditions of the regular channels change. D-c signals which indicate the condition of each radio channel are passed to the receiving switch control equipment. The receiving switch control equipment passes d-c signals to the receiving i-f switch equipment and also passes voice-frequency control signals over the wire-line facilities to the control circuits at the transmitting end of the switching section. The latter control circuits pass d-c signals to the local i-f switches in the transmitting switching equipment.

The power to operate this equipment is obtained from the common power plant of the *TD-2* radio system at each location. The same safeguards which relate to power or equipment failures are also employed in this case.

Operation of a Switching Section

Under normal conditions, one to five regular channels of the *TD-2* radio system operate in their normal manner and one channel, the protection channel, carries an 8.5-mc identification signal. This pilot signal is above the normal base-band information frequencies transmitted by the *TD-2* radio system and is inserted into the protection channel at the transmitting end of each switching section.

Each radio channel, including the protection channel, is continuously monitored at the receiving end of the switching section. This equipment monitors the noise level in a narrow band above the base-band information on each channel. Trouble in any channel is indicated by an increase in this noise level or a loss of carrier.

The protection channel is substituted for any regular channel by the following series of events. The monitoring equipment sees an increase in noise level above the threshold value required for a switch. D-c signals are sent to that particular area of the receiving switch control equipment associated with the regular radio channel in trouble. The receiving switch control equipment prepares to operate the receiving coaxial i-f switches which will substitute the output of the protection channel for the output of the failed regular channel. However, the output of the protection channel is still without base-band information except for the 8.5-mc identification signal. The receiving switch control equipment, which prior to the "trouble alert" condition has been sending a 700-cps (cycle-per-second) guard signal over the wire-line facility toward the transmitting end of the switching section, changes the signal to 900, 1,100, 1,300, 1,500, or 1,700 cps depending upon which regular radio channel has requested assistance. The control circuits at the transmitting end of the switching section recognize the change in the voice-frequency signal, know which regular channel is to be switched, open the normal connection on the protection channel, and bridge the input of the protection channel to the regular radio channel indicated by the voice-frequency wire-line signal. Thus, the same base-band information is now being sent over the

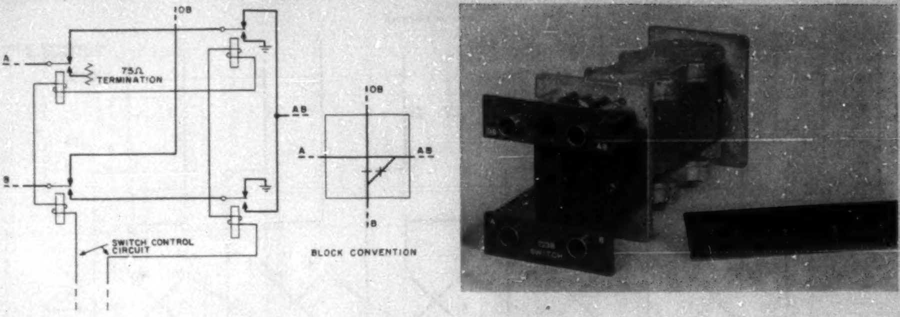

Fig. 4. A 223-type i-f coaxial switch

regular radio channel and over the protection radio channel. At the receiving end of the switching section, the monitoring equipment assigned to the protection channel recognizes that the 8.5-mc signal has disappeared, indicating that a regular channel signal is now being received via the protection channel facilities. If the noise and carrier levels in this latter signal are satisfactory, then d-c signals are sent to the receiving switch control equipment. The proper receiving switch, which was alerted when the failure was first detected, is now operated and, thus, the switch to the protection channel is completed.

The switching always takes place in the 70-mc coaxial circuits. In addition to connecting the desired signals to through paths, the otherwise open-ended coaxial circuits are terminated in the 75-ohm characteristic impedance of the coaxial equipment. During the progress of the switching operations described in the foregoing, alarms are sent to control centers and to the receiving end of the switching section.

The regular channel is returned to normal operation by the following series of events: When the regular channel becomes normal, the noise and carrier level return to normal and the d-c switch control instructions to the receiving control equipment are cancelled. The i-f switches at the receiving end of the switching section are released and the regular channel is returned to normal service. However, the protection channel is still bridged to the regular channel at the transmitting end of the switching section. This bridge is released by the transmitting switch control circuits when it receives a 700-cps guard tone over the wire line. This guard tone replaces the higher frequency voice-frequency signal on the wire line at the same time that the receiving i-f switches are released at the receiving end of the switching section. When the i-f switches at the transmitting end of the switching section are released, the protection channel is returned to normal and will again transmit its 8.5-mc identification signal. The monitoring equipment, upon seeing this signal, returns its circuits to normal.

SERVICE INTERRUPTION CAUSED BY SWITCHING OPERATIONS

The time required for a switch to complete is dependent upon the sum of the recognition and operate times of the receiving-end equipment, the transmitting-end equipment and the time of transmission of orders over the voice-frequency wire-line facilities. The maximum time objective for a switch to complete is 50 milliseconds and the usual switch is completed in 30 to 50 milliseconds. In the case of a sudden failure, the radio channel is open for this period of time. In the case of slower failures because of fades, etc., the switch request is started before the signal becomes unusable. Usually, the service will not be affected. During the more rapid fades, a television viewer may see the background noise of his picture increase and then suddenly disappear as the switch is completed.

SWITCHING SAFEGUARDS

The chaos which would be possible without safeguards to co-ordinate each operation of the switching equipment to allow for failure of the switching equipment or to prevent a single trouble from tying up a transcontinental route is obvious. The following illustrate the possible situations which have been allowed for in the design of the switching equipment.

Failure of the Switching Equipment

Failure of a fuse associated with an individual channel unit will affect only the switching equipment assigned to that one radio channel. In the case of equipment common to all channels, failure of any fuse or any component such as an electron tube, resistor, coaxial switch, etc., will cause the switching equipment to maintain the status quo at the time of equipment failure or to return the system to normal operation. In any case, the reliability of the *TD-2* radio system will not be less than it would have been without the automatic-protection switching equipment.

Simultaneous Failure on Two Channels

The switching equipment has only one protection channel available and cannot take care of two simultaneous troubles within one switching section. However, the probability of such troubles is reduced by limiting the number of repeater stations within a switching section. When two troubles do occur within a switching section, the first channel to get its request to the control circuits at the receiving end of the switching section takes priority. Once the protection channel is substituted for the first channel to request a switch, then no other switch orders will be accepted until the first regular channel has returned to normal service.

Single Failure Causing Switch in Subsequent Switching Sections

The switching equipment does not interchange information between switching sections. However, failure of the signal in any radio channel is seen by all subsequent switching sections. Every switching section will initiate a switch

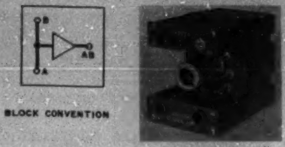

Fig. 5. I-f bridging amplifier

and, when the protection channel is bridged to the regular channel at the transmitting end of all switching sections subsequent to the section containing the trouble, the signal transmitted over the protection channel will also be unsatisfactory. Therefore, the receiving-end monitoring and evaluating equipment will not cause the switch to be completed at the receiving end. In the switching section containing the trouble, however, the signal seen at the receiving end of the section will be acceptable and the switch will be completed. Subsequent switching sections will then see a good signal over the regular channel and the switch requests will be cancelled.

Incomplete Switch Tying Up Entire System

The switching equipment must complete a switch within 50 milliseconds or the system will lock out that switch request for 10 seconds and accept any other switch request. This feature is known as recycling, which means that, if two switch requests are received and, for some reason, the first switch request cannot be completed, then, after 50 milliseconds, the first request will be ignored and the second request will be accepted as though no other request were present. In the event that no other second request is present at the end of the 10-second period, then the first request for a switch will be processed for 50 milliseconds. This routine is continued until either the first request is cancelled or the switch is completed.

CO-ORDINATION OF SWITCHES AT TRANSMITTING AND RECEIVING ENDS OF SWITCHING SECTION

The equipment at the transmitting end of a switching section is completely slave to the equipment at the receiving end of the switching section where all decisions are made. The receiving-end control equipment can only send one voice-frequency signal toward the transmitting-end equipment at a time, and the 700-cps guard tone is always transmitted before another identification voice-frequency signal is transmitted. The transmitting-end control circuits can accept only one order at a time and will not honor any new orders until the previous order has been cancelled by reception of the 700-cps guard tone. Thus, both ends of the protection radio channel are substituted for the same regular radio channel.

SWITCHING AT INTERMEDIATE POINTS ALONG THE ROUTE

In television service, one or more radio channels may be dropped at points along the route between the ends of the switching section. If a failure occurs between the transmitting end of the switching section and the point where a television drop takes place, then the service to the television drop also fails. No matter where the failure occurs in the switching section, transfer of service to the protection channel will necessitate shifting all drops on that regular channel to the protection channel also. These situations are provided for by what has been termed auxiliary station switching equipment. This equipment is similar to the equipment at the transmitting end of the switching section, except that: 1. the i-f switches do not bridge the protection channel to the defective regular channel but rather bridge the television drop for the defective channel to the protection channel; and 2. the control equipment actuates the i-f switches only after the switch has been completed on the over-all switching section and a supplementary 2,100-cps voice-frequency signal has been received over the wire line. The system is restored to normal by the same 700-cps guard tone used to restore normal conditions at the transmitting end of the switching sections.

ALARMS

Each trouble condition causes an alarm. These alarms are indicated at the receiving end of a switching section and may be duplicated at remote locations. A summary of the alarms are as follows:

1. A major alarm is operated when a regular channel fails and is not replaced by the protection channel within a few seconds.

2. Minor audible and visual alarms are operated to indicate failures on the regular or protection channels when the failure, lasts for more than 15 to 45 seconds. In the case of a regular channel failure, service must be provided via the protection channel. In the case of protection channel failure, all the regular channels must be in normal operating condition. The visual alarm indicates the number and direction of the channels in trouble.

3. A major alarm is also operated within a few seconds if the protection channel fails after it has been switched for an impaired regular channel or for use as an additional channel.

4. A major alarm is operated if the pilot supply for the protection channel fails at the transmitting end of a switching channel or if the pilot supplies used in the evaluating circuits fail.

5. Minor audible and visual alarms are operated to indicate failure of a voice-frequency path. Two alarm lamps are lit for a failure. One lamp indicates that a voice-frequency path is in trouble and the other indicates the direction of transmission affected.

MANUAL CONTROLS

Even automatic switching systems must be turned on and off and be manually switched for repairs and equipment or circuit rearrangements. A control panel at the receiving end of the switching section, equipped with lamps to indicate the condition of the circuits, also contains push-button switches for locking out the switching system or manually switching the system. This panel may be duplicated at remote points by d-c connection. A master button and the button representing the operation desired must be depressed together; this feature prevents accidental operation of the equipment. Various types of manual switches are possible. One type of manual switch requests a switch of a regular radio channel in much the same fashion that the automatic equipment requests the switch. In this case, the 50-millisecond timer is disabled and the switch will not be completed if service via the protection channel is not satisfactory. However, there are situations where, for service or other reasons, it is desired to switch definitely over to the protection channel. In this case, there is a forced manual switch button. Another type of switch involves the regular channel lockout which is requested when operating conditions warrant removing any regular channel from the protection of automatic switching. In other instances, traffic may be such that the protection channel is required for regular service in addition to the other five channels. In this case, the protection channel lockout button is depressed and, if the protection channel is not at that time being used as a substitute for a regular channel, then the automatic switching equipment is locked out of service and the reliability of the *TD-2* radio system reverts to that of the unprotected system.

EQUIPMENT AND CIRCUIT ARRANGEMENTS

The same basic building blocks are used at the transmitting end, at the receiving end, and at the auxiliary stations of a switching section. These include the

223-type coaxial switch, i-f bridging amplifier, regular and protection channel switch initiators, pilot supplies, and control circuits. Figs. 2 and 3 respectively show the schematic of the transmitting-end and receiving-end coaxial switches and bridging amplifiers which may be inserted in the transmitting and receiving i-f switch bays respectively of Fig. 1.

Coaxial Switch

The *223*-type coaxial switch shown in Fig. 4 performs the actual switching operations. The switch is designed for use on 75-ohm coaxial circuits carrying signals in the 70-mc range. The switch has four transfers which operate simultaneously when power is applied and crosstalk between circuits is 90 db or greater. The switching elements are glass-enclosed reeds which operate in 1.5 milliseconds. Positive contact is obtained by liquid mercury which wets the reeds by capillary action. The switch housing is a die-cast assembly and the power and coaxial connections are made by separable connectors.

I-F Bridging Amplifer

The i-f bridging amplifier is shown in Fig. 5. This amplifier has a single coaxial input and two coaxial outputs. The path from *A* to *B* is a low-pass filter with a cutoff above 400 mc, and transmission from 60 to 80 mc is flat. The path from either *A* or *B* to *AB* passes through a 1-tube amplifier which is usually adjusted for unity gain. Failure of the electron tube will not cause failure of the path *A* to *B*. Similar to the coaxial switch, the housing of the amplifier is die-cast and all connections are by means of separable connectors.

Regular and Protection Channel Initiators

The initiators contain the evaluating circuits. They accept a 70-mc signal from each radio channel and an 8.9-mc tone from a local signal generator. D-c control signals representing the condition of the received signal are passed to the control circuits. The initiator contains an f-m receiver in which the 8.9-mc tone amplitude-modulates the 70-mc carrier signal. The base-band output of the receiver contains the television or message information plus the 8.9-mc tone. If the carrier is lost, then the 8.9-mc tone is also lost to the output. The evaluating circuits analyze the 8.9-mc tone and the noise level in a narrow band around it. The protection channel initiator is similar to the regular channel initiator except that the evaluating circuits analyze the 8.5-mc tone and the narrow noise band about that frequency so as to determine the condition of the protection channel. The initiators are of conventional chassis construction for 19-inch-wide duct-type bays, and all of the initiators at the receiving end of a switching section are mounted in one bay, as shown in Fig. 6.

Pilot Supply

The 8.9-mc signal which is fed to the initiators is supplied by a pilot supply at the receiving end of each switching section. This unit contains two separate oscillators with a *223*-type switch and automatic transfer circuits to maintain output in the event that one oscillator fails. Construction is similar to the initiators.

Protection Pilot Resupply

This unit is used at the transmitting end of each switching section to supply the pilot information for the protection channel. Since the radio frequencies are not converted to base-band information at each repeater station and, hence, at the ends of some of the switching sections, this supply must provide the equivalent of an 8.5-mc tone frequency-modulated on a 70-mc carrier. Conventional mechanical construction is used similar to the other pilot supply equipment.

Filters

The automatic protection switching system depends upon analysis of the narrow band of information located about 8.5 and 8.9 mc in the base-band information. Although the input to the *TD-2* radio system is not normally expected to contain information at these frequencies, pilot-blocking filters are inserted in each radio channel at the input to the f-m terminal transmitters of the *TD-2* radio system to wipe this area of the band clean. These filters are of conventional filter design and are mounted with the terminal equipment.

Control Circuits

The control circuits are a combination of electromagnetic relay and electron tube circuits. The receiving-end control equipment generates the voice-frequency signals for use as guard tone, channel identification frequencies, and the 2,100-cps tone for the auxiliary station supplementary control signal. In addition, this receiving-end equipment times the switching operations, provides the recycling, and controls the receiving-end coaxial switches. The transmitting-end control equipment analyzes the voice-frequency signal received from the receiving-end equipment and controls the transmitting-end coaxial switches. This equipment also is of the conventional relay rack panel design.

Bay Arrangements

Although each direction of transmission of the *TD-2* radio system and the associated automatic protection switching is independent, 2-way service is provided over the *TD-2* radio system route and, hence, automatic protection switching is usually provided on a 2-way basis. Thus, at each end of the switching sections, transmitting-end equipment and receiving-end equipment generally will be provided. The initiators require an entire bay at each location, as shown in Fig. 6. However, the i-f switches can be mounted in a single bay, as shown in Fig. 7. Additional space in this bay may be used for other equipments which are not part of this protection system. The control circuits can be housed in one bay, as shown in Fig. 8.

Other Uses of Component Parts

The building blocks of this switching system have been adapted for other uses with the *TD-2* radio system. As indicated in Fig. 7, maintenance switching has been used to substitute other equipment on a maintenance basis. Program switching is another use.

Conclusion

Automatic protection switching for the *TD-2* radio system was put into service on the Denver and Sacramento route in June 1954. Since that time, other routes have been equipped with this protection. Tests and service observations have shown that the automatic protection switching system is providing marked improvement in the reliability of the *TD-2* radio system.

An Instrument to Record Voltage Flicker

V. H. KRAYBILL
MEMBER AIEE

H. M. JENSEN
ASSOCIATE MEMBER AIEE

A VARIETY of electric devices have come into use in industry which impose rapid and frequent changes of load. This may cause sudden changes in voltage at frequent intervals, a condition which is known as voltage flicker. It is the concern of the electrical utility to detect such flicker to keep it below the level at which objectionable lamp flicker results.

It was found desirable to have an instrument which would give a continuous record of voltage changes. This could be connected to record the voltage at distribution substations or at any suitable location. If at any time the voltage flicker exceeded permissible values, an investigation could be made to determine the cause of the flicker and remedial action could be taken.

General Description

Certain difficulties are encountered in attempting to measure flicker voltage with conventional recording instruments. Since the voltage changes are very rapid and of short duration, most recording meters will not respond fast enough to follow these changes. Even though an instrument was available which would follow these variations, and which had a scale with sufficient expansion to show them, it was not practical to obtain a continuous record of all voltage changes. These changes are likely to occur several times a minute, and a chart with a speed suitable for continuous operation would be solidly inked. It would then be impossible to distinguish the individual voltage changes. For example, a 1-volt drop in voltage level followed by an additional 1-volt drop a few seconds later would appear as a 2-volt drop. However, the resulting lamp flicker would be that of two separate voltage drops of 1 volt each.

In reference 1 more details of the problems involved in measuring voltage flicker are given, two devices which were designed for this purpose are described and further references to other methods which have been used are mentioned. These other means of measuring voltage flicker have been designed primarily for staged tests, in which a complete record of voltage variations have been obtained for a short interval of time with the use of oscillographs with relatively high-speed charts or cameras. The device described in this paper records on a standard graphic voltmeter with a chart speed suitable for continuous operation. It does not give a record of voltage level or of all voltage variations but only records sudden voltage drops exceeding

Fig. 1. Block diagram of the flicker recorder

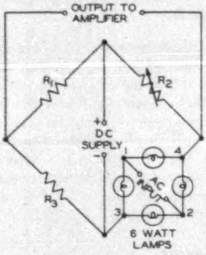

Fig. 2. Simplified diagram of the bridge circuit

certain predetermined values. Even though such voltage drops occurred rapidly enough to ink solidly the chart, the record still showed that the individual voltage drops had exceeded certain values. The exact number of such variations could not then be determined, but this is not generally required. A counter could be used in connection with the device to obtain that information.

The device was built to record three ranges of voltage flicker. For example, a drop exceeding 1.0 volt but less than 1.5 volts would move the pen to one-fourth of full scale on the chart. A voltage drop between 1.5 and 2.0 volts would give a deflection of one-half of full scale, and any drop exceeding 2.0 volts would record at three-fourths of full scale. By simple adjustments, these ranges can be set at any value from a fraction of 1 volt to several volts of flicker on a 120-volt base.

A time delay is provided which allows the use of the standard graphic voltmeter. Regardless of the duration of the voltage drop, the pen reaches the proper deflection and returns to zero before it responds to another voltage drop of the same or smaller magnitude. However, it is designed so that a voltage drop in a higher range will be recorded, even though it occurs while the pen is deflected for a lower value.

The response time of the recording meter limits the rate at which flicker voltages can be recorded. The limit of the device built is about one deflection per second. If the flicker occurs more often than this, the device continues to record at that rate. However, an output jack is provided on the device to which a higher speed oscillograph may be connected to record the exact rate of flicker. This record may be calibrated to obtain the actual value of the voltage drops rather than the voltage range normally recorded.

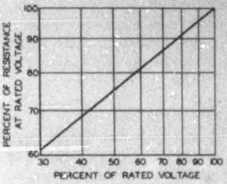

Fig. 3. Resistance characteristics of a 6-watt lamp with change in voltage

The measuring instrument itself does not have instantaneous response. There is a thermal lag introduced by the incandescent lamps used in the measuring circuit and an additional delay in the filtering circuit. In the present design, the over-all time of response is about 9 cycles (on a 60-cycle-per-second circuit). Voltage drops of shorter duration than this appear to be of less than the true value. If required, this response time could be reduced somewhat by a change in the circuit design.

An important consideration in designing the instrument was to use a measuring circuit which would respond to the drop in rms voltage rather than average or peak values. This is important when measuring flicker voltage produced by resistance welders or electric arc furnaces since the current is often nonsinusoidal and the voltage wave form may therefore be distorted. The rms voltage is desired because that is the value which determines the amount of lamp flicker.

Block Diagram

The components of the flicker recorder are shown by the block diagram of Fig. 1. The voltage being measured is connected to the bridge circuit through an isolating transformer. The nominal input voltage is 120 volts. The power requirement of this input is approximately 12 watts.

With a constant voltage input, the output of the bridge circuit is a direct voltage which is a function of the rms value of the input voltage. Changes in the input voltage will produce a varying direct voltage output. This voltage is applied to a 2-stage resistance-capacitance-coupled amplifier. This circuit is designed so that only the rapid variations in the voltage are amplified. If the input voltage is constant, the amplifier output is zero. The input voltage level affects only the grid bias of the first stage.

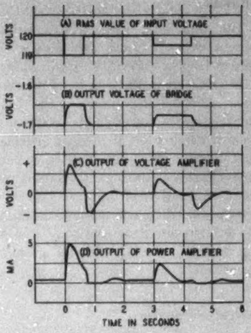

Fig. 4. Voltage and current changes at certain locations in the measuring and amplifying circuits when a change occurs in the voltage being measured

The output of the voltage amplifier is connected to a power amplifier which operates three sensitive relays. These relays may be adjusted to pick up at the desired values of voltage flicker. For example, one relay may operate with a 1.0-volt drop, with the other relays set for higher values. The relay contacts control auxiliary relays which operate the graphic voltmeter, the deflection depending on whether one, two, or three of the relays pick up. Therefore, a record is obtained which shows that the voltage flicker exceeded certain predetermined values. The auxiliary relays seal in, allowing time for the recording pen to reach the proper deflection. A time-delay relay then operates to allow the pen to return to zero.

Circuit Description

BRIDGE CIRCUIT

The detection of voltage variation is accomplished by the bridge circuit as shown in simplified form in Fig. 2. This bridge detects the change in resistance of lamp filaments resulting from a change in the applied voltage. This resistance varies with the temperature of the filament and is, therefore, a measure of the rms value of the voltage. The curve of Fig. 3 shows the relationship between the resistance and the voltage for the lamps used in the bridge. With a logarithmic voltage scale, this is a straight line over the range shown. Therefore, the percentage change in resist-

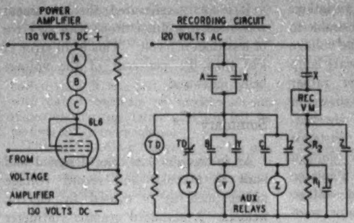

Fig. 5 (left). Simplified diagram of the power amplifier and recording circuit

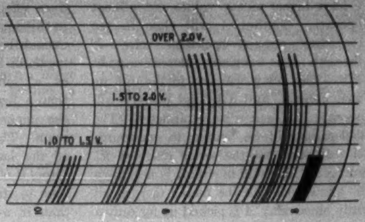
Fig. 6 (right). Record obtained on graphic voltmeter



ance will be the same for a given percentage change in voltage at any point on the curve. The operating point varies with the voltage level but this does not affect the calibration since the instrument is used only to detect rapid voltage changes. Aging of the lamps may shift the position of the curve slightly but, if the slope remains the same, the calibration will not be affected. Since the lamps are operated at only half voltage, there is very little aging effect and the life of the lamp is practically indefinite.

As shown in Fig. 2, the circuit consists of two bridges with the output terminals of the first bridge connected as one arm of the second bridge. The voltage to be measured is applied to terminals 1 and 2 of the first bridge which consists of four 6-watt incandescent lamps. Since the four arms of this bridge are identical, it remains balanced at any voltage. The purpose of the bridge connection is to balance out the alternating voltage at terminals 3 and 4. At these terminals, the bridge appears as a resistance which varies with the alternating voltage applied to terminals 1 and 2.

The other three arms of the second bridge are wire-wound resistors. A direct voltage is applied to this bridge, which is operated slightly unbalanced. Resistor *R2* may be adjusted to obtain the desired voltage output for a particular value of alternating-voltage input to the first bridge. Changes in this input will produce a change in the output of the second bridge. The final result is therefore a direct-voltage output which varies with the rms value of the alternating-voltage input.

In the actual circuit, a filtering capacitor is connected across terminals 3 and 4. A small 60-cycle voltage may otherwise appear across these terminals because of slight differences in the resistance of the four lamps. A 120-cycle component is also produced as the resistance changes during each half-cycle of alternating voltage. Additional filtering is provided at the output of the second bridge and in the following amplifier.

There is a component of direct current in the lamp circuit but its heating effect is small compared with the a-c component. The d-c supply is regulated to eliminate voltage variations from this source which would appear in the output of the bridge.

VOLTAGE AMPLIFIER

The output of the bridge circuit is connected to a voltage amplifier. A 2-stage resistance-capacitance-coupled amplifier is used. The output of the amplifier is a voltage pulse which occurs with each rapid change in voltage input. With a constant voltage input, the output voltage is zero.

The curves of Fig. 4 show the voltages which appear at various points in the circuit when a voltage change occurs. Curve *A* shows the rms value of the voltage input to the bridge circuit. The voltage drops shown are typical of those produced by an electric welder. The output of the bridge circuit is shown by curve *B*. The voltage changes are not instantaneous because of the thermal delay of the lamps and a delay in the filtering circuit.

The circuit parameters of the voltage amplifier are chosen to obtain a satisfactory response to this signal. The output voltage of the amplifier is shown by curve *C*. A voltage drop produces a positive pulse and a voltage rise results in a negative pulse. This signal is applied to a power amplifier.

POWER AMPLIFIER AND RECORDING CIRCUIT

A simplified diagram of the power amplifier and recording circuit is shown in Fig. 5. The power amplifier operates three sensitive relays, shown as *A*, *B*, and *C*. The pickup current of each relay may be adjusted with shunting resistors not shown in the diagram. Relay *A* is set for the lowest pickup value.

The output current of the power amplifier is shown by curve *D* of Fig. 4. A voltage drop will give a positive current pulse as shown. Since this tube is biased nearly to cutoff, the output current is zero for even a small negative signal. Therefore, only voltage drops are used to operate the relays.

The contacts of relays *A*, *B*, and *C* are used to operate auxiliary relays *X*, *Y*, and *Z* in the recording circuit. These, in turn, control the deflection of the recording voltmeter. For example, assume that a voltage drop of 1 volt occurs, as shown by curve *A* of Fig. 4. If the pickup value of relay *A* is adjusted to 5 milliamperes, it will just operate with this voltage drop. Relays *B* and

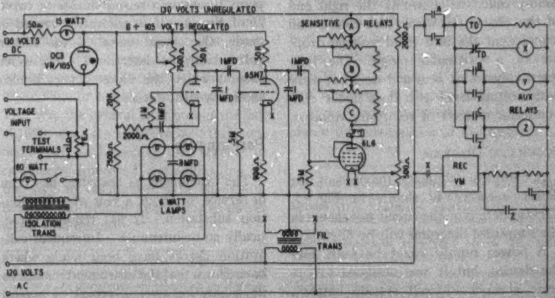


Fig. 7. Schematic wiring diagram of flicker recorder

C have higher pickup values and will not operate. Contact *A* will close in the recording circuit, operating relay *X* through the normally closed contact *TD*. This relay will seal in through its own contact, and a second contact will operate the recording voltmeter. The deflection will be limited to one-fourth of full scale by the series resistors *R1* and *R2*. The seal-in circuit is necessary to allow time for the meter to respond fully since relay *A* is picked up for only a few cycles. The coil of a thermal time-delay relay is also energized by the seal-in contact *X*. After a time delay, contacts *TD* open, dropping out relay *X* and de-energizing the recording meter. The circuit is then ready to record another voltage drop.

Assume that relay *B* is adjusted to pick up with a voltage drop of 1.5 volts and that relay *C* will pick up with a 2.0-volt drop. With any value between 1.5 and 2.0 volts, both relay *A* and relay *B* will pick up. The circuit will operate as described in the foregoing and, in addition, contact *B* will close to pick up relay *Y* which seals in. Resistor *R1* is by-passed by contact *Y*, allowing the voltmeter to reach one-half of full scale. If the voltage drop is over 2 volts, relay *C* will also pick up, operating relay *Z* which by-passes resistor *R2*. The meter deflection is then three-fourths of full scale.

A voltage drop may occur during the time the relays are sealed in and the meter is deflected. If this voltage drop is in a higher range than that being recorded, the meter will be deflected to the higher value. A voltage drop in the same or lower range will have no effect.

A reproduction of the record obtained on the recording meter is shown in Fig. 6. Three voltage ranges are shown for which the instrument might be calibrated. If the voltage flicker is occurring rapidly, the record will be solidly inked, as shown at the right end of the chart. However, the record still shows that the individual voltage drops are in a particular range. The base line is always at zero and does not vary with voltage level as it does in the conventional method of recording voltages.

SCHEMATIC DIAGRAM

A complete schematic diagram of the flicker recorder is shown in Fig. 7. Certain details of the circuit not shown in the simplified diagrams will be discussed.

A power supply could be built into the device, but it was designed to operate from a 130-volt station battery. A voltage-regulating tube is used to reduce effectively the voltage variations in this source. It was found desirable to extend the operating range of the voltage regulator by using a small 15-watt lamp as a voltage-dropping resistor rather than a fixed resistor. This is shown in the upper left-hand corner of the diagram. The decrease in the resistance of the lamp filament, as the voltage across it is reduced, permits the regulator tube to start at a lower supply voltage than it would if a fixed resistor were used of the resistance value required to limit the tube current to its rated maximum value when the voltage supply is at its maximum.

The voltage to be measured is connected to the terminals labeled "voltage input." A calibrating circuit is provided which may be used to produce the desired voltage drop. With a 60-watt lamp as shown, any drop between zero and 3 volts may be obtained by adjusting the rheostat to the proper value and operating the push button switch. If the source of voltage to be measured has insufficient capacity, any other 120-volt a-c source may be used for calibrating.

The supply voltage to the power amplifier is unregulated. However, the circuit design is such that variations in this voltage have a negligible effect on the output current. The effect of a change of plate voltage is compensated by the change of bias voltage which is obtained from the same source through a voltage divider.

The relays are calibrated by changing the bias of the power amplifier tube and by adjusting the shunting resistors across relays *B* and *C*. These resistors are arranged in a network designed to reduce the effect of an adjustment of one relay on the other relays.

An output jack is provided in the plate circuit of the power amplifier tube. An oscillograph may be connected at this point to obtain a record similar to curve *D* of Fig. 4. If a calibration record is made, the actual value of the flicker voltage may be determined. The exact rate at which the flicker occurs is also shown by such a record.

Performance

The instrument as described has been in service for about a year at a distribution substation. It has required practically no maintenance. Infrequent calibration checks have been made which have shown that the instrument maintains its calibration over a period of several months without adjustment.

If properly calibrated, the instrument will measure voltage drops with an error of less than 0.1 volt. This is an error of less than 0.1 per cent of the voltage being measured.

Summary

An instrument has been designed and built to measure and record voltage flicker such as is caused by electric welders. A standard graphic voltmeter is used to record voltage drops which exceed certain predetermined values. A time-delay circuit permits recording voltage flicker which occurs too rapidly for a graphic voltmeter to respond fully.

The instrument responds to the rms value of voltage. The graphic voltmeter records three ranges of voltage flicker. The actual value of the voltage flicker may be measured by connecting an oscillograph to the instrument. This will also give the exact rate at which the flicker is occurring.

Discussion

O. Ramsaur (Pennsylvania Power and Light Company, Allentown, Pa.): The instrument described can be used as a simple means of continuously monitoring the voltage at a given location to detect the presence of sudden voltage drops and to record the approximate magnitudes and times of occurrence of noticeable drops. This should be quite adequate in many cases and will determine whether further information is needed in any case.

The popular curves of flicker tolerance are based on magnitude of voltage change and on the frequency of occurrence. It would be interesting to know how the several magnitudes of dips and their frequency are used in deciding whether voltage fluctuations are tolerable or intolerable. This question has bothered us for a long time.

Since the instrument records only sudden drops in voltage, it is probably assumed that for every sudden drop there will be a corresponding sudden rise. This would hold for fixed loads like electric welders but would not hold for spasmodic loads like arc furnaces. Our experience indicates that a sudden rise in voltage is just as annoying as a sudden drop of the same amount. It is noted that the term voltage "change" is used in several places in the paper where "drop" is meant.

It is noted that a 60-watt lamp is used as a calibrating load. It would seem to me that the inrush current of the lamp would lead to considerable errors because: 1. The recorder operates during the period before stable voltage change is reached and 2. for frequent operation, the inrush current will depend upon how long the lamp filament has cooled since it was last used. Experience with circuit breakers on model railroads indicates that the latter effect is felt for periods of 2 or more minutes.

The use of an a-c bridge as one leg of a d-c bridge is both clever and new to me. It avoids some of the difficulties in other methods of measuring small changes in voltage.

F. W. Warburton (New England Power Service Company, Worcester, Mass.): The authors have added a new and ingenious instrument to assist in a solution of the flicker-voltage problem. Within the range of this instrument, to those needing a record of the time that voltage dips occur, as well as their number and duration, the device should be of considerable assistance.

In my experience the major phase of the problem has been concerned with spot welders having time deviation from 1.5 to 4.5 cycles. Some multicylinder compressors have caused six to eight voltage dips per second, a region of maximum irritation. These dips were mostly 0.5 to 1.0 volts on a 120-volt basis. Unfortunately, the orders of brevity and frequency involved are out of range of the authors' instrument.

It would be interesting to know the error in voltage drops of shorter duration than nine cycles when the described device is operated on a 60-cycle system, and how the authors propose to shorten this 9-cycle limitation.

Southwest Oregon Radio System for the Bonneville Power Administration

D. J. MARIHART
ASSOCIATE MEMBER AIEE

D. L. WYLIE
MEMBER AIEE

THE southwest coast line of Oregon is rugged, primitive, and beautiful. From Gold Beach, near the Oregon-California border, the towns of Port Orford, Bandon, Coos Bay, Reedsport, and Mapleton lie on the sea at the foot of the coast range in a northward sweep of 144 miles.

A Bonneville Power Administration (BPA) 115-kv line serves this area. Starting at Eugene, the line penetrates the coastal range via the Siuslaw River valley, reaching the coast near Florence. From this point, it runs southward, paralleling U. S. Highway *101* and reaching a southern terminus at Gold Beach. Intermediate substations are served at McKinley and Norway in addition to stations located at the towns previously mentioned, see Fig. 1.

The coastal range, in the 300-mile section south of Eugene, is traversed by only three main roads. Rain forest covers peaks ranging in elevation from 1,500 to 3,600 feet from bases at sea level. Rainfall on the western slopes averages 75 inches per year. For several months in the winter, snow up to 18 inches is experienced at elevations above 2,000 feet.

Important rivers flowing seaward are the Siuslaw at Florence, the Umpqua at Reedsport, the Coquille at Bandon, the Sixes at Sixes, and the Rogue at Gold Beach. All flood in the spring. The commerce of the area depends mainly upon the growing logging and forest product industry and ocean fisheries.

The BPA line to this area is the only large-scale source of power and the region is dependent upon it. Each year, spring gales with gust velocities up to 120 miles per hour take their toll of the area and the power line. Concurrent with the storms, heavy rainfall brings rivers to flood stage. Washouts of Highway *101* and branches are numerous. It is not uncommon for the area between Coos Bay and Gold Beach to be isolated and without electric power for periods of 1 to 3 days. Extensive losses to property and losses of life are experienced.

The job of prompt restoration of power lines, in the past, was complicated by the lack of communications following storms. Telephone service to this area was by wire lines. These usually went down in the early phases of the storms. With lines down, several radio amateurs in Coos Bay and vicinity were able to make sporadic contact with Eugene and other points. BPA line trucks equipped with medium-frequency (mf) radio sets operating on 2,222 and 4,880 kc were able to make some contact with each other and with Eugene while en route to the coast. Often the first job was to open Highway *36* down the Siuslaw valley and to remove many large fir trees from across the road. This was the general situation in the fall of 1950, when it was determined that, as a matter of public safety and service to customers, improved communication to the area in connection with the maintenance and prompt restoration of power was a vital necessity.*

Communications Requirements

It was determined that a radio network was needed to meet operating conditions. Communications requirements of the network are as follows:

IMMEDIATE

1. A 2-way party-line voice-conversation circuit between J. P. Alvey load-dispatching headquarters, Eugene, Oreg., and each of the coastal substations.
2. Very-high-frequency (vhf) and mf radio systems to provide coverage pattern over all lines and substations in the area. The design is to permit radio-equipped maintenance vehicles in the area to maintain continuous 2-way conversation with the J. P. Alvey dispatcher.

FUTURE

In line with projected growth of the area and the resultant increase in load demand, it was also necessary to consider the following probable future requirements:

1. Need for a second voice channel between J. P. Alvey substation and the southwest Oregon maintenance office at Coos Bay.
2. One or more telemetering channels between the aforementioned points.

While the future requirements were not controlling in the initial phase, there appeared a high probability that one or both would become a necessity within 5 years following energization. Consequently the planning of the entire system was tempered by these considerations.

A team was immediately organized to check the possibilities of utilizing one of

* The West Coast Telephone Company in cooperation with the Pacific Telephone and Telegraph Company has since improved telephone service considerably by placing in operation in October 1954 a 900-megacycle (mc) ultrahigh-frequency (uhf) system between Eugene, Florence, and Coos Bay.[1]

Paper 56-700, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 28, 1956; made available for printing April 30, 1956.

D. J. MARIHART is with the Bonneville Power Administration, Portland, Oreg., and D. L. WYLIE, formerly with the Bonneville Power Administration, is now with the Chicago, Milwaukee, St. Paul and Pacific Rail Road Company, Chicago, Ill.

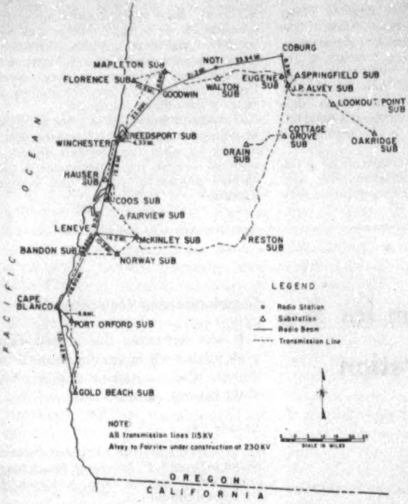

Fig. 1. Southwest Oregon radio system, location map

two available systems of communication. Attention was given first to possible expansion of the BPA mf radio network operating in the 2,222/4,880-kc band. Since the experience with this band had shown it to be generally unreliable during mid-day, attention was also directed to the possibility of a new vhf system operating in the 162- to 174-mc government band. This latter band has now become the standard for the BPA system replacing progressively the mf operation.

Three radio-equipped cars were used, one car was equipped with mf radio and two with 25-watt vhf sets. Directional corner-reflector type of antennas and portable masts supplemented the vhf equipment.

Office work prior to the survey consisted of checking U. S. Geodetic Survey quadrangle maps and BPA power facility maps to determine suitable routes and vhf repeater stations for the vhf system. It was known from the nature of the terrain that repeater stations would be necessary. Average airline distance between substations was 30 miles, and the substations were all at low elevation with surrounding land masks of varying magnitude. As has been previously noted, the problem of providing good vhf communications to the substations and along the lines was complicated by their separation from J. P. Alvey substation by the coast range.

Three separate routes were considered over the mountains. Of necessity, these were chosen to follow the highways over the mountains and are listed in the following in order of preference:

1. The Siuslaw Valley route via Coburg, Noti, and Mapleton; the route ultimately adopted is shown in Fig. 1.
2. The Umpqua Valley route via Drain, Elkton, and Reedsport.
3. The Bone Mountain route via Roseberg, Bone Mountain, and Norway.

Routes 2 and 3 were of interest as future planning called for new transmission lines in this area.

Profiles were drawn between prospective repeater stations on each of the three different routes. A typical profile is shown in Fig. 2. Stations were selected from the standpoint of available access roads, nearness to electric power (a difficult problem in this area), availability of land, minimum site elevation (the determining factor in winter being snow cover of site and access roads), and proximity to BPA substations and transmission lines which are necessary for good vhf coverage. The preliminary surveys were completed in 1 week.

Vhf signal strength readings were taken in terms of microvolts measured at the receiver input. Checks were made between each of the substations and each of the proposed repeater station sites. The preliminary data indicated that: 1. mf radio coverage could be obtained on a part-time basis between McKinley substation, Coos Bay substation, and J. P. Alvey; and 2. an economical vhf system could be installed with a maximum of five repeater stations. These stations would provide communications to all the BPA substations in question, and under all the 115-kv lines in the area for mobile-equipped line-maintenance trucks. Since the mf system could not provide coverage for all stations, it was eliminated from future consideration.

At this juncture it was realized that design factors predicted a dual system. A uhf or superhigh-frequency (shf) point-to-point backbone would be required, controlling vhf radio stations at the repeater and terminal points, for area coverage of the lines and substations. Available government band frequencies for the point-to-point system were: band *a*, 406 to 420 mc; band *b* 1,700 to 1,850 mc; and band *c*, 6,525 to 7,525 mc.

Single-channel equipment was known to be available operating in band *a*. Multichannel equipment was available from several manufacturers for operation in bands *b* and *c*.[2,3,4] A report was compiled, complete with cost estimates recommending a combination microwave and vhf radio system. Fig. 3 shows a block diagram of the system as constructed.

Point-to-Point Microwave Links

The southwest area dispatching headquarters is located at J. P. Alvey substation and is connected with J. D. Ross substation near Portland by a Federal Telephone and Radio-Corporation type-*10C* microwave system. It was decided to start the radio system to the coast from the Coburg microwave site, with the use of one of the 23 voice channels between Alvey and Coburg as the first link in the system. From Coburg, additional shf links were established as follows:

	Path Length, Miles
Coburg-Noti lookout	23.4
Noti lookout to Goodwin lookout	21.2
Goodwin lookout to Winchester	23.9
Winchester to Leneve	31.2
Leneve to Cape Blauco	28.9

Vhf links were used to extend service from the repeater aforementioned points to the various substations. As the microwave system ends at Cape Blanco, the final extension to Gold Beach substation, the southern terminus of the system, is by vhf. Since the communications conditions differ between individual re-

peaters and substations, a brief résumé will be given for each point.

1. Noti: A vhf land station is arranged for continuous omnidirectional transmission to mobiles operating between Eugene and Greenleaf on Highway *36*.

2. Goodwin: A vhf land station is arranged for continuous omnidirectional transmission to substations and mobile units. It provides communications to Mapleton and Florence substations as well as highway coverage from Greenleaf to Winchester Bay. Vhf radio equipment at Mapleton and Florence substations is arranged for push-to-talk half-duplex directional transmission to the shf station.

3. Winchester: A uhf land station coverage of Highway *101* from Florence to Coos Bay. The service to Reedsport and Coos substations is on the same basis as in point 2.

4. Leneve: A vhf land station coverage of Highway *101* from Winchester Bay to Bandon. It serves the McKinley and Norway substations on a nonline-of-sight path on the same basis as in point 2. The service to Bandon is the same as for Norway and McKinley, except that the beam path is line of sight; see Fig. 4.

5. Cape Blanco: A vhf coverage from Bandon to Gold Beach. The service to Port Orford and Gold Beach substations is on the same basis as in point 2.

Fig. 3. Southwest Oregon radio system, block diagram

A temporary mf station was installed at McKinley Substation, an interchange point with the California-Oregon Power Company, to provide interim communication until the vhf system could be installed. The project in entirety was approved in May 1952, with system energization scheduled for January 1, 1954. The work involved in providing this communication system can be divided into four main categories:

1. Field surveys.
2. System design.
3. Equipment specifications.
4. System installation and operation.

Field Surveys

Surveys were made to determine the following:

1. Microwave point-to-point path clearances.

2. Vhf field strength along roads, lines, and on nonline-of-sight paths.

3. Station elevations, and elevations of critical points.

4. Location of station sites, access roads and power lines.

5. Co-ordination data for the joint occupancy of U. S. Forest Service lookouts at Goodwin and Noti.

Microwave paths were checked with the use of heliographs in daylight and high-power lamp techniques at night. Terminal and intercept points were triangulated in the field and cross-checked in the office with data from a Kelsh plotter as derived from aerial stereo pairs.

Vhf field strengths on nonline-of-sight paths were established with the use of a 25-watt base station with a 36-foot portable mast and a quarter-wave whip antenna;

Fig. 5. Portable vhf test station

see portable vhf test equipment, Figs. 5 and 6. At the receiving end, a corner reflector and calibrated receiver were employed. On the intercept paths to Mapleton, McKinley, Norway, and Port Orford, reception was from waves diffracted over intervening ridges.[5] Careful check was made to determine the values of nulls and maximums in the standing wave pattern.

Access roads to microwave sites varied in length and condition. At Winchester, 1,200 feet of new road were needed. Twelve miles of existing U. S. Forest Service road were used at Goodwin with some crushed rock improvement of soft spots. An existing 3-mile access road was used at Cape Blanco, the site of a U. S. Coast Guard Loran station. The balance of the sites were served by existing county roads or highway *101*.

Power lines were a more difficult problem. It was necessary to contract with local utilities for power service extensions to repeater sites as follows:

Noti lookout: Construct 2 miles of new line.

Goodwin Peak: Construct 7 miles of new line.

Winchester Bay: Construct 600 feet of new line.

Leneve: Construct 2 miles of new line.

Fig. 6. Close-up of test equipment in Mobile

Fig. 7. Power line to Goodwin Peak

The line construction to Goodwin Peak was especially difficult, as can be seen from Fig. 7 which shows one span of the line.

At all other sites, power at distribution voltages was available. Costs for initial construction of the lines listed in the foregoing were substantial and proved that in virgin terrain the costs of roads and power lines are often controlling factors in the design and ultimate costs of the system.

System Design

BUILDINGS

Prefabricated modular aluminum buildings are used at all repeater sites. These are $10^{1}/_{2}$ feet in width and with lengths variable in 2-foot increments from 14 to 20 feet. Separate rooms with outside entrances are provided for emergency power and radio equipment. Buildings are constructed at the central shop, trucked to sites, and there mounted on a previously erected concrete base slab.

Equipment consists of fluorescent lighting, an automatic fire extinguishing system in the emergency power room, and thermostatic space heaters in the equipment room. Actual on-site pictures of buildings are shown in Figs. 8 and 9.

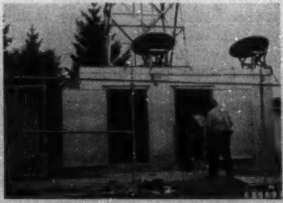

Fig. 8. Noti radio building, looking north, front view, with doors open showing close-up of engine generator room, radio equipment room, and parabolic antenna mounting

Fig. 9. Noti radio building, inside view showing close-up of engine generator equipment on left and radio equipment on right

TOWERS

Three general types are employed. The first is a 50-foot self-supported lightweight-steel transmission type with top-mounted platform. The second is a 50-foot guyed, wooden H-structure. The third is a guyed steel lattice pole tower with 2-foot cross section, adapted from a standard dead-end tower.

The 50-foot self-supporting towers are located at Noti and Goodwin, since two reflector antenna combinations are used at these points. The Noti tower is shown in Fig. 10. At Cape Blanco a guyed wood H-frame is used. This is shown in Fig. 11. Note that the building is also guyed. This site is on a rocky promontory jutting into the Pacific

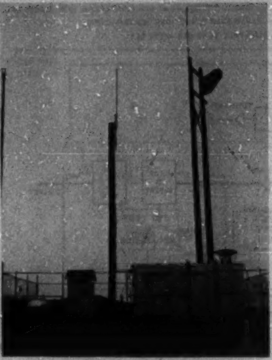

Fig. 11. Cape Blanco, looking west. Front view with door closed showing guys

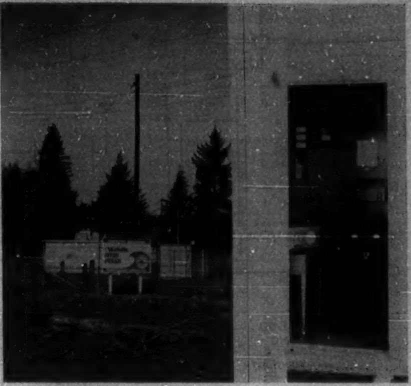
Fig. 13. Reedsport substation, looking north. Front view of control house with doors open. Control console is shown on table to left of vhf radio panel



Ocean. Winds of 120 miles per hour in gusts have been recorded.

A 120-foot guyed lattice pole is used at Winchester and a similar tower of 175-foot height at Leneve. Use of these towers made it possible to span a close intercept between the two stations. The tower at Leneve is shown in Fig. 12.

All towers are designed for 0.25-degree torsional deflection and 0.5-degree vertical deflection under maximum wind and ice load conditions. The 4- by 6-foot reflectors used on all towers have an approximate 3.5-degree beam width at operating frequency.

Equipment Specifications

In accordance with specifications covering the purchase of system components, the following basic system was obtained:

EMERGENCY POWER

Kohler 5-kva propane-driven engine generators, single phase, 60 cycles, 117 volts a-c, equipped with automatic starting, stopping, and transfer of load were installed. At each location, except Noti and Winchester, 200-gallon tanks are used which provide sufficient reserve for a 10-day operation. At Noti and Winchester 500-gallon tanks provide a 30-day reserve.

VHF RADIO INSTALLATION

Motorola 25-watt vehicular-type vhf radio equipment is installed at Substations. Equipment at five substations, Florence, Coos Bay, Port Orford, Norway, and Bandon, provides a 6-volt operation from a *200 AH* battery supply and charger. Balance of stations have 117-volt a-c equipment, with emergency supply from rotary converters operating on 24-volt batteries.

The 6-volt stations are unattended, the radio equipment being turned on only when the operator is at the station. Stations at Mapleton, McKinley, Reedsport, and Gold Beach have operators and use 117-volt equipment, which is equipped with annunciators so that the dispatcher may call the operator. The layout of Reedsport substation is shown in Fig. 13.

A 117-volt a-c 50-watt vhf base-station equipment is used at all microwave repeater points. Twelve BPA maintenance trucks were initially equipped with vhf mobile sets. A close-up of the control head and installation are shown in Fig. 14.

SPECIAL FEATURES

The vhf system incorporates the following unique features:

1. Base stations operate at full duplex at all times, using transmit frequency of 172.525 mc and receive frequency of

168.325 mc. Transmitting and receiving antennas are physically spaced both vertically and horizontally. With this spacing and 4-mc frequency separation, cavities are not required to prevent receiver desensitization.

2. Any substation or mobile unit may selectively call the dispatcher or the attendant switchboard operator at J. P. Alvey substation. The system terminates on a multiple basis on the dispatchers Western Electric *508A* switchboard and on the Western Electric type-*551* attendant private branch exchange. Calling lamp and buzzer are provided together with interchange of "busy" indication. A picture of the type-*508A* switchboard is shown in Fig. 15. Outbound calling on the system is voice-call, with all land stations energized, a requirement of the BPA branch of operation.

3. Mobiles by means of hand-set push-to-talk buttons may select the closest of several vhf base stations within range and cause it to connect automatically to the microwave link for in bound transmission to Alvey. At Alvey, the inbound channel is normally connected to the outbound channel so that any mobile using the link automatically rebroadcasts over the entire area. Under these conditions, the dispatcher can override to take control when desired. He is therefore able to take charge of the system and talk or monitor at all times. Block diagrams of the controls on mobiles and at base stations are shown in Figs. 16 and 17. When the mobile operator pushes the "dispatcher" selective call button, he starts the vhf transmitter and simultaneously modulates it with a 2,550-cycle-per-second (cps) audio tone. This audio tone is received at the vhf base station, decoded, and used to start another 2,550-cps tone generator which sends the tone to the dispatcher headquarters at J. P. Alvey. At J. P. Alvey it is decoded and used to operate the calling lamp and buzzer on the telephone switchboard. The dispatcher operates his answer key, thereby energizing a 3,000-cps tone generator which transmits its tone on the outbound leg of the microwave audio channel. The 3,000-cps tone is received at each vhf land station, decoded, and used to turn on all the vhf transmitters.

4. Mobiles are equipped with two transmitters and one receiver, normally transmitting on f_2 and receiving on f_1. They work with the base station which transmits on f_1 and receives on f_2. When direct mobile-to-mobile communications are desired, the operator may switch the car transmitter to frequency f_1. These transmissions do not interfere with transmissions between base stations and mobiles in other areas. Since receivers are always tuned to f_2, the mobile may be contacted by the dispatcher at any time by voice call.

MICROWAVE POINT-TO-POINT SYSTEM

The specifications permitted radio equipment suppliers to bid on either uhf or shf equipment. Philco *CLR-6* microwave radio equipment was low bid. Operation is in the 7,125- to 7,425-mc shf band, and provides the backbone system.

The audio base band is used. There being no special multiplexing equipment, the system operates with amplitude and frequency modulation. System fade margins are set at 20 decibels per hop (about 3/4 decibel per mile). *F1A* weighted signal-to-noise ratio for a single hop is about 50 decibels. Under idle channel conditions the outbound and inbound voice channels are connected at Alvey so that a true party-line system is provided.

An automatic audio tie, with directional sensing, permits the system to operate in parts in the event of failure of a repeater station. Thus, if the Winchester station fails, the Leneve–Gold Beach portion operates as a fully independent system, as does the Goodwin–J. P. Alvey section. This is a valuable feature. A block diagram of the sensing system is shown in Fig. 18. A 2,850-cps tone generator at Cape Blanco continually sends a tone to J. P. Alvey, on the inbound leg of the audio channel. Since the microwave audio channel is looped at Alvey, the tone is received at all the microwave stations on the outbound leg also. If it is not received on the outbound leg at a particular station, that station will switch to terminal, and automatically complete the audio loop.

An alarm indicator system at J. P. Alvey records the basic fault conditions at each microwave station. These are: 1. east-to-west radio-frequency failure; 2. west-to-east radio-frequency failure; and 3. emergency power plant operating. Inbound alarms are by sequential time-coded tones.

The alarm equipment is important in pin-pointing troubles since economic

conditions did not permit radio-frequency stand-by equipment at the stations, although the system is designed to permit addition of stand-by equipment at a future date.

Components of System Cost

Table I represents the breakdown of costs, in percentages, on this particular job, and gives an indication of what may be expected in locations of this nature for systems of the type outlined. Of the items listed in Table I, engineering, radio equipment, housing, towers, emergency power, and test and energization are quantities that may be accurately estimated. Factors in which large cost uncertainties were found to exist in this case were the site development, commercial power, and roads. Tower costs were substantial but often cheaper than additional repeater stations. In this case, the high towers at Winchester and Leneve obviated the need for an intermediate station originally planned.

System Installation and Operation

The backbone system consisting of all the microwave links and two vhf links was installed in a record-breaking 6 months after it was placed on order. The remainder of the system consisting of seven vhf links was installed 18 months after the backbone system.

Several interesting problems were encountered during the installation period. The first involved a low fade margin on the Leneve-to-Cape Blanco microwave link. Approximately one-third of this link is over water. Since it was imperative that cost be held to a minimum on this particular system, no precautions were taken against unusual fades such as were known to exist on other over-water paths. During 2 months of operation, the microwave radio-frequency signal strength charts recorded fades greater than 25 decibels. A typical chart recording is shown in Fig. 19. This was serious and resulted in momentary system outages, since the fade margin for this link was set at 25 decibels. Steps were immediately taken to replace the 4-foot parabolic antenna and the 4-by-6-foot reflector at Leneve with a 6-foot parabolic antenna and a 6-by-8-foot reflector respectively. The larger

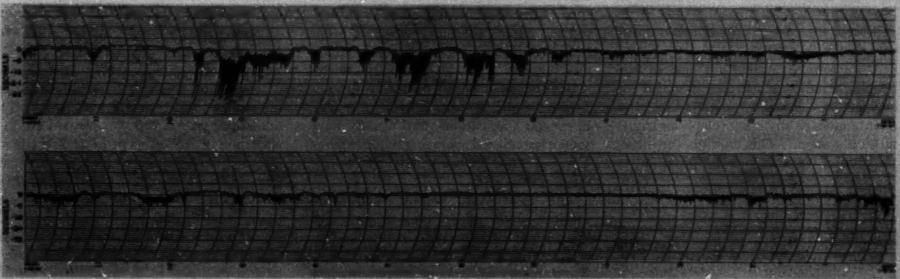

Fig. 19. Cape Blanco–Leneve microwave received signal chart recording

antenna and reflector provided an additional 8-decibel fade margin for a total of 33 decibels on this path. No momentary system outages caused by fading have been recorded or noticed since this change was made.

The second problem concerned the difference in phase at J. P. Alvey between dispatcher audio signal tones picked up at two different microwave stations. This problem was solved by adjusting the vhf receiver noise squelch sensitivity at the base stations to cut out weak signals and by reducing the power output of the Bandon vhf station so that the signal received at Cape Blanco was less than the vhf station squelch setting.

The third problem was discovered in November 1955 during a major power system outage in southwest Oregon. The power system frequency dropped to 57 cps at the microwave station but the voltage remained at 117 volts a-c. Since no frequency-sensitive relays were initially provided in the emergency power switch-over equipment, the engine generator set did not start. The voltage regulators on the microwave power feed, being of the resonant circuit type, caused the alternating voltage to the microwave to be too low for the equipment to function properly. This problem was solved by replacing the low-voltage-sensing switch-over relay with a dual-purpose low-voltage frequency-sensing switch-over relay.

The fourth problem was caused by lightning. Lightning struck the vhf antenna on top of the 175-foot Leneve tower, travelled down the coax, and burned out the radio-frequency receiver tuned-circuit input. The solution to this problem was the installation of a quarter-wave short-circuiting stub across the vhf receiver radio-frequency input.

The operation of the entire system has been planned. Recently, one of the microwave repeater stations was operated for a period of 3 months with no maintenance, as a result of land slides which made the service road impassible. It has not been found necessary to service the vhf equipment at the substations more often than once every 2 months. Over-all system in service time during 1955 was better than 97 per cent. It is possible that radio-frequency stand-by equipment would bring this figure up to 99.7 per cent. This would be comparable to the in service time achieved on BPA microwave systems in Washington and northern Oregon.

Microwave for Telephone Companies

W. C. FISHER
MEMBER AIEE

MICROWAVE is considered very carefully before it finds itself in the toll plant of a telephone company. To an even greater extent than other communication services, telephone companies require microwave to be capable of the utmost in performance and reliability, and yet be economical. In fulfilling these obviously contradictory requirements, microwave must meet the unusual and exacting specifications of the telephone plant and, often at the same time, compete with the cost of time-honored open-wire and cable facilities.

A microwave system for use in the telephone industry must be designed for engineering, ordering, installation, and maintenance as any other telephone transmission system. This requires the incorporation of features and the provision of services which are often unfamiliar to the radio industry, but which are based on long-established telephone engineering practices.

Microwave systems range in size from small, packaged terminals that provide two or three channels to elaborate equipment capable of simultaneously carrying several color television channels and hundreds of telephone channels across the continent. They can be divided into three categories: heavy-route, medium-route, and thin-route systems. The heavy-route, or large-capacity systems, use Western Electric type-*TD-2* microwave, and are generally well known. The 1- to 3-channel systems are generally used in special applications, and usually have somewhat relaxed operating requirements. These systems are not widely used by the telephone industry.

The in-between system, known as medium-route microwave, is not well known, yet it is the type of facility that is most applicable to the average telephone plant. A typical telephone office installation of medium-route microwave equipment is shown in Fig. 1. There is no distinct division between medium- and heavy-route, or medium- and thin-route microwave; however, it is expected that the capacity of medium-route systems will eventually reach several hundred telephone channels. At least one system now in use can be expanded, in groups of 12 channels, to an ultimate capacity of more than 350 channels. At present, such medium-route microwave systems are being used by many telephone companies ranging from small Independents to Bell System Telephone operating companies.

Two frequency bands are most commonly used for common-carrier service. These are from 890 to 940 mc (megacycles), and from 5,925 to 6,245 mc. A distinct advantage of the former is that it allows the use of relatively inexpensive, flexible r-f (radio-frequency) transmission lines. This permits physical separation of the antenna and the microwave equipment and, thus, a versatility in regard to installation of the transmitter and receiver. The 900-mc equipment can always be installed indoors and, consequently, gets the advantage of routine maintenance at the system terminals. An advantage of the 6,000-mc band is the wider available bandwidth which permits larger numbers of channels to be transmitted without interference.

Paper 56-699, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 19, 1956; made available for printing May 15, 1956.

W. C. Fisher is with the Lenkurt Electric Company, Inc., San Carlos, Calif.

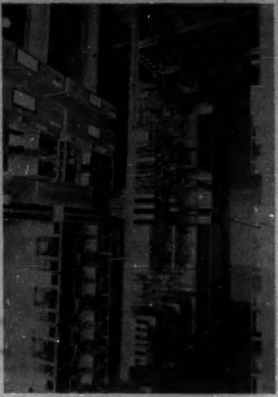

Fig. 1. Typical telephone office installation of medium-route microwave equipment

Basic Requirements

Telephone companies are usually operated by men with long experience in the techniques of communication by open-wire and cable. Consequently, to prove-in and be accepted, medium-route microwave must meet the majority of the following requirements:

1. Installation cost should be below that of an open-wire or cable system capable of providing the same number of channels. Installation costs include all costs incurred up to the line-up of the microwave system.
2. Quality of transmission should be equal to or exceed that of an equivalent open-wire or cable system.
3. Reliability and life expectancy should be comparable to that of other electronic equipment in the telephone toll plant, such as carrier telephone and telegraph equipment.
4. Microwave equipment must be mechanically and electrically compatible with other telephone equipment.
5. Maintenance cost should be equal to or less than that of an equivalent open-wire or cable system. Maintenance procedures should be simple enough to require little extra training of maintenance personnel.

A microwave manufacturer, in attempting to meet these five requirements, must realize that the provision of microwave equipment is only the beginning in fulfilling a telephone company's needs. Many other factors concerned with the installation, operation, and maintenance of the system take on as much significance as the characteristics of the basic radio equipment itself.

Fig. 2. Typical remote microwave repeater site

Installation Costs

Installation cost is one of the most important of the five basic requirements of microwave for the telephone industry. An important part of the total installation cost may be the cost of the microwave equipment. This is especially true for relatively simple installations. In many cases, however, particularly where large antenna structures, emergency power supplies, power lines, access roads, and buildings are involved, the cost of the radio and carrier equipment may be only of incidental importance. Fig. 2 shows a typical remote-repeater station in which the cost of the transmitting and receiving equipment was only a small part of the total installation cost. Fig. 3 shows a simple pipe-mounted antenna for a relatively inexpensive microwave installation.

Of the many items contributing to the initial cost of a microwave installation, several factors, which are under the control of the manufacturer, are important in keeping the first cost as low as possible. These factors include the design of equipment especially for telephone use, the construction of equipment that promotes easy installation, and the provision of information and instruction material for telephone personnel. Another factor reducing initial cost is the availability of a completely engineered microwave system instead of component parts which then require expensive engineering coordination. Also, accurate and up-to-date engineering and ordering information supplied by the manufacturer saves time in writing specifications and requisitions and assures complete delivery of the equipment.

An important purpose in keeping the first cost of a microwave system to a minimum is to improve its competitive position with respect to open-wire and cable facilities. At present, the prove-in distance of a single-section microwave system may be as short as 15 miles. For distances less than this, cable and cable carrier still appear to be the most appropriate facilities. In the future, however, improved and more economical microwave techniques may be expected to reduce the prove-in distance to less than 15 miles.

Fig. 3. A simple pipe-mounted antenna installation

An instance is known where a single-section 48-channel system was installed over a 17.5-mile path between two cities. At each end of the system, antennas were mounted on pipe masts on top of the telephone company office buildings. In engineering the system, a comparison was made between the cost of the 48-channel microwave and an equivalent cable installation. It was determined that cable would have cost about $4,500 more than the radio and multiplexing equipment installed and ready for service. In this particular case, the difference in cost was important; but the deciding factors were the expandability, reliability, and the ease and simplicity of installation of the microwave. Table I gives a comparison between the installation costs of an expensive and of a simple installation.

Transmission Quality and Performance

Medium-route microwave usually is expected to provide transmission facilities for part of, or all of, one link in the nation-wide toll network. It is therefore necessary for the microwave system to have characteristics which maintain satisfactory toll-quality performance.

The four most important transmission characteristics of a microwave system are flat frequency response, level stability, frequency stability, and adequate signal-to-noise ratio. The first three usually are the least troublesome to the microwave manufacturer because they represent areas in which conventional radio engineering techniques are applicable.

Table I. Comparison of Costs Between an Expensive and a Simple Installation

Expensive Repeater Installation, Dollars		Simple Terminal Installation, Dollars	
Land and building	25,000	Antenna support	500
Access road	18,000	Installation and accessory equipment	1,000
Antenna supports	6,000	Radio equipment†	8,000
Installation and accessory equipment	80,000	Total	9,500
Radio equipment*	20,000		
Total	149,000		

In an average installation, the microwave equipment cost amounts to less than 50% of the total installation first cost.

* Radio equipment cost is 13.5% of total cost.

† Radio equipment cost is 84% of total cost.

The operational characteristic which gets the closest scrutiny by telephone engineers is the ability of the microwave to provide a transmission medium in which all carrier channels are within the noise limits prescribed by accepted toll standards. The noise contribution of the microwave is the factor which limits, more than any other single characteristic, the system's length and channel capacity.

In the engineering of links (toll trunks) for the nation-wide toll dialing system, a frequently quoted objective is the maintenance of total long-term (more than 50% (per cent) of the time) average noise below +31 dba (decibels adjusted). The noise measurement quoted is at a zero-level transmission point with *F1A* weighting. The noise level per link may rise above this for small percentages of the time.

A link may be made up of combinations of cable, wire line, and microwave in tandem. Therefore, the microwave system's noise contribution will be limited to a value which is the difference between the accepted standard and the added noise power contribution by the cable, wire line, and channelizing equipment. Since each application of microwave involves different factors, it is necessary that the manufacturer provide accurate noise performance data to the telephone transmission engineer.

The noise contributed by the microwave system comes from three main sources:

1. The modulator of the transmitter (modulator noise).
2. Intermodulation distortion caused by nonlinearities in the microwave equipment.
3. The head end of the receiver (receiver thermal noise which is of principal interest during fading).

The importance of the noise contributions from these sources depends upon the number of repeater sections in a system, the section lengths, and the propagation path clearances. The noise produced by each source must be kept as small as design and manufacturing techniques will allow because individual noise contributions are additive on a power basis.

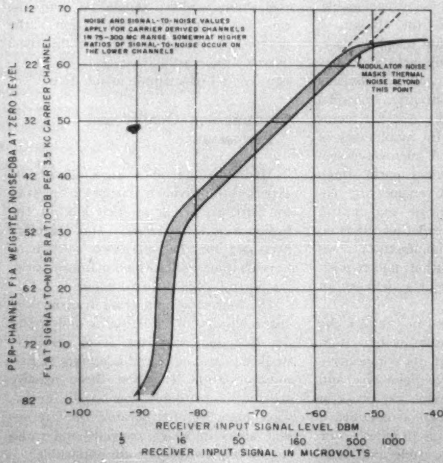

Fig. 4. Thermal noise characteristic of a Lenkurt type-72B 900-mc frequency-modulated microwave receiver

Modulator noise can be minimized by good equipment design, but can never be eliminated. A typical microwave transmitter for telephone use will generate about +14 to +16 dba of such noise.

Intermodulation distortion is a more complex noise source. The linearity of the modulator, demodulator, and wide-band amplifiers under peak-load conditions determines the amount of noise contributed as intermodulation distortion. Loading depends upon the type of carrier system, the peak number of channels in use at one time, and the talker levels.

Complete and accurate information on the performance of the microwave equipment with respect to intermodulation distortion must be provided by the microwave manufacturer. These data are needed by the transmission engineer before he can design a system consistent with the established transmission standards. A typical microwave system loaded with 120 telephone channels, operating in accordance with accepted loading statistics, will contribute intermodulation noise of about +16 dba to each carrier channel during 1% of the busy hour.

Thermal noise in the head end of the receiver is caused by the random motion of electrons in the input resistance and in components of the receiver located before the first amplifier stage. For an adequately designed microwave system, thermal noise will have no significance during normal propagation conditions. Thermal noise has to be taken into account only during the time that fading occurs. The thermal noise data for a receiver should be provided by the manufacturer. A set of curves such as that illustrated in Fig. 4 will give complete information.

When the noise characteristics of the channelizing equipment, the modulator noise, the intermodulation distortion, and the thermal noise characteristics of the

microwave equipment are known, the noise performance of the over-all system can be calculated for both normal and faded propagation conditions. With noise factors of the magnitudes described, microwave toll systems employing single-side-band suppressed-carrier channelizing can be extended to 10 or 15 repeater sections without resorting to the use of compandors or heterodyne repeaters. Section lengths up to at least 55 miles are possible, depending upon the type of terrain to be traversed and the clearance which can be obtained.

Heterodyne repeaters, while capable of reducing noise in long systems, lack flexibility for dropping and inserting channels at repeater and branching points. Such flexibility has proved advantageous in many medium-route installations. Furthermore, maintenance is standardized when back-to-back microwave terminals are used as repeaters.

Reliability

To provide the high degree of reliability required by the telephone industry, the microwave equipment must utilize the highest quality of components. Adequate metering must be provided, power supplies should be conservatively rated and adequately fused, and the entire system should be provided with monitoring and alarm circuits so that troubles can be localized immediately. Equipment arrangements should be such that all components and panels are easily replaceable.

Where equipment is installed at unattended locations, and particularly where the need for exceptional reliability is important, a suitable remote-control and supervision system should be installed. The remote-control and supervision system should operate over a facility independent of the system it supervises. In the Bell Telephone System, the supervisory and control signals of many *TD-2* routes are carried over paralleling open-wire, cable, or radio systems.

Frequently, medium-route systems do not have adequate paralleling facilities, and may be required to carry their own remote-control and alarm tones. Since a working system is needed to convey supervisory information and, since the most important information concerns unserviceable equipment, stand-by microwave becomes essential. In fact, for maximum reliability of service, stand-by microwave equipment and an adequate remote-control and supervision system go hand in hand. Fig. 5 shows an array of microwave equipment and its associated remote-control and supervisory equipment for use in the telephone network of the Hawaiian Islands.

Reliability is also dependent upon freedom from fading. The results of extensive operating experience, particularly in the vicinity of 900 mc, have made it possible to engineer systems with conservative repeater section lengths up to 55 miles which are almost completely free of fades.

Performance records of 99.80% for single-section systems without stand-by and 99.98% for multisection systems with stand-by are being achieved by operating companies using routine maintenance procedures. Of course, the higher degree of reliability can be obtained only when stand-by microwave equipment is installed, particularly where unattended installations are involved. When these performance records were being determined, the systems were charged with the outage time caused by equipment failure, the traveling time to get to the unserviceable equipment, and usually with the time the systems were turned down for routine servicing.

The requirement for long life of microwave equipment is related to the requirement of reliability. A telephone company should expect its microwave equipment to serve in the toll plant for at least as long as its associated carrier telephone and telegraph equipment. This imposes an obligation upon the microwave manufacturer to design and supply equipment of good quality, and then be ready and willing to stock spare parts and to provide spare panels for an indefinite number of years, even if manufacture of the equipment has been discontinued.

Compatibility

Microwave equipment specifically designed for use in the telephone industry must include features not usually found in radio equipment used for other types of service. These features include:

1. The same general mechanical characteristics as in other telephone equipment.
2. Circuit design and layout in accordance with conventional telephone practices.
3. Electrical characteristics co-ordinated with other telephone equipment.

The physical arrangement of microwave equipment should be such that it can be used anywhere in the toll plant. The advantages of housing microwave equipment without restrictions in any convenient location are immediately apparent. One of the hurdles which radio has had to overcome in the highly standardized telephone industry is its "special" nature. Special equipment, installed on a roof or in a hut, does not take advantage of the constant routine checking and maintenance procedures long established as standard telephone practice.

Experience is proving that microwave equipment, easily accessible in the central office and simply tested, is maintained as easily and performs as reliably as its associated carrier equipment. To make such routine maintenance possible, drawings, engineering information, and maintenance practices along lines standardized by the telephone industry must be made available by the microwave manufacturer.

Conventional telephone engineering practices should be followed in the design and construction of the radio equipment to facilitate installation, investigation of trouble, and maintenance. Also, the equipment should include all necessary safety practices for protecting personnel from the risk of shock.

Electrical co-ordination requires that impedances and levels, particularly on the drop side of the microwave equipment, be identical to those encountered in the connecting carrier equipment. The microwave supplier should provide, on a co-ordinated basis, the necessary junction filters, amplifiers, equalizers, pads, impedance-matching transformers, and other accessory items that permit the telephone company to achieve the utmost flexibility in the use of the microwave equipment. Also, some means should be provided to monitor the microwave circuits, to switch automatically to stand-by microwave equipment, and to include alarms which indicate that the equipment has failed.

The actual cost of maintaining the microwave system must be kept as small as possible, within the standards of reliability. This requires equipment that can be checked and adjusted by telephone craftsmen as part of their routine duties. Maintenance practices should enable nonspecialist craftsmen to localize troubles and make repairs. Here again, it is extremely important that any changes in design be co-ordinated with changes in instruction material so that the equipment and the drawings agree in every detail.

Engineering and Installation Services

In the telephone industry, the engineering load on operating companies is often relieved by placing orders with the supplier for entire communication links. The supplier then takes on the responsibility for engineering the system into the telephone company's plant, ordering all items of equipment, and installing and lining up the system. After completion of line-up, the working system as well as suitable technical data are turned over to the telephone company. At least two suppliers are currently involved in providing such service to the telephone industry.

Statistics on Typical Microwave Systems

It is possible here to provide statistics only on Lenkurt Electric Company, Inc., microwave systems. These statistics should be of some interest however, because they account for more than 40% of the medium-route microwave systems in use by the telephone industry.

Tables I through VII give statistics for the Lenkurt Electric Company, Inc., microwave systems installed or presently under construction. Of 31 systems, 18 have been for independent companies and 13 have been installed by the Bell Telephone System operating companies. The average section length is 23 miles, with the maximum length at 56 miles and the minimum at 5.5 miles. The average system consists of two sections and requires one repeater. Almost 40% of the repeaters have branching or drop-off arrangements, which is a provision not conveniently obtained with heterodyne repeaters. The cost of the microwave equipment may range from about 10 to over 80% of the total cost of the installation. Most systems thus far installed use separate antennas for transmitting and receiving, but several have been equipped with r-f directional filters to permit transmission and reception on a common antenna.

Conclusion

The nature of the telephone industry is such that its suppliers must assume certain immediate and long-term responsibilities that are different from those in other industries. These responsibilities transcend the manufacturing and furnishing of a high-quality piece of radio equipment, and include such factors as design and performance intended specifically for telephone use, the supply of accurate and complete information concerning the system, the guarantee of a continued supply of spare parts and panels, and a continuous up-to-date information service.

Although the initial cost of a microwave system is important, many factors often combine to cause the first cost to lose much of its significance. Such factors are transmission quality, performance, reliability, life expectancy, compatibility with other equipment, and maintenance costs. Regardless of a system's initial cost, unless it fulfills the requirements and continues to do so, it is of little value.

Traffic Considerations in Community Dial Offices

S. J. LANIGAN
ASSOCIATE MEMBER AIEE

T. J. McDONOUGH
MEMBER AIEE

THE Rural Electrification Administration (REA) under an Act of Congress of October 1949, has the responsibility for making long-term loans for the construction of telephone systems in predominantly rural areas. Security for loans of this type is represented primarily by the ability of the system to provide good service at reasonable rates over the loan period. To insure that the systems for which loans are made represent adequate loan security, it is necessary to establish standards for the design and construction of such systems. It is the purpose of this paper to discuss some traffic engineering standards used by the more than 50 consulting engineering firms who design the systems.

Existing Traffic Objectives

Community dial offices in REA borrowers' systems are usually equipped for conditions anticipated 3 years after cutover. Certain components, battery, charger, building, etc., that are not economically reinforced in a period as short as this will operate initially at lower efficiency so as to last for longer periods. In general, it is preferred that designs be kept convervative because with the planned 3 years' growth there is normally ample time to engineer and install an addition before service deteriorates to the point where there are customer complaints. With the tendency of the suppliers to go more and more to interchangeable components and to jack-in equipment, there is a possibility in multiexchange systems economically to transfer equipment not only within the office but between offices. Intraoffice trunking is based on traffic estimates given in the central office equipment specification. Traffic tables are included in the specification in which the grades of service for the various ranks of switches are as follows:

Linefinders [less than 100% (per cent) lockout]	0.01*
Linefinders (with 100% lockout)	0.02*
Second selectors	0.02
Connectors from second selectors	0.01
Connectors from first selectors	0.03
Revertive call switches	0.01
CLR trunks to local switchboard	0.01

*Approximate.

It may appear to some that these grades of service are better than required to satisfy rural subscribers. It is important to realize that many of the subscribers are on multiparty lines with seven or more others. When a subscriber does succeed in finding the line idle, the probability of finding the called line idle is less than for the average urban system because it too is more than likely a multiparty line. To have the same subscriber receive a busy condition regularly because of insufficient central office equipment will lead to subscriber complaints. Another aspect of this is the fact that even with these criteria, for the average system of REA borrowers, central office equipment (including toll terminal equipment) accounts for only 15% of the total investment in plant.

Since almost 90% of the dial central offices in the borrowers' systems are less than 200 lines, as a general rule the only traffic information furnished the switchboard supplier is the anticipated originating busy hour traffic on a per line basis. In addition to other information about interoffice trunk circuits, the number in the group, their function, and physical length are furnished. The switchboard suppliers compute the interoffice trunk traffic assuming, unless there is information to the contrary, (1) the busy hour condition for the individual ranks of switches occurs at the same time, (2) traffic on 2-way trunks is equal in each direction, and (3) the following table applies:

	Trunk Mileage	
	Less than 8 Miles	More than 8 Miles
Extended area service (EAS)	$P = 0.05$	$P = 0.10$
Toll	$P = 0.03$	$P = 0.05$

Any grading that is required is engineered by the supplier as is the determination of the number of linefinders, selectors (except those associated with the interoffice trunk circuits), and connectors. The reason for leaving this item open is to invite the most economical design of equipment. Some manufacturers furnish 100-point linefinders, others 200-, another effectively 250-, and one has the equipment arranged so that in small offices on outgoing calls the linefinder-connector is released after the trunk has been found and as in the case with other manufacturers, incoming trunks terminated on connectors do not use the local connectors on incoming calls.

Although terminating of trunks on line circuits was very popular among the independents, by 1950 there were several reasons favoring not doing it. The one which had always been present was the fact that incoming trunk calls would then tie up a linefinder as well as a selector and/or connector. The increased usage of these circuits might require an additional intraoffice trunk which would cost more than terminating the trunk on a switch. About 1950, operator toll dialing placed a limitation of one wait for dial tone on incoming calls. This means that where there was a tandem connection to the toll dialing network, either the end office or the tandem office must have its trunks terminated on switches. At about the same time the elimination of manual switchboards caused extended area service to be introduced at a more rapid rate. This, coupled with the introduction of 2-letter, 5-digit numbering and the desirability of universal numbering between dial exchanges, made the use of directing codes and the waiting for dial tones at intermediate points undesirable. The borrower's engineer determines whether or not to terminate trunk circuits on line circuits, selectors, or connectors. There are some installations in REA borrowers' systems where EAS or short-haul toll trunks are terminated on line circuits but usually the distant point has a manual switchboard.

For the past few years all dial switchboards purchased by REA borrowers have had their local first selectors wired for digit absorbing and the majority of them have been equipped for digit absorbing. From now on all local first selectors will be equipped for digit absorbing, although it may not be utilized during the initial period. The borrower's engineer furnishes a numbering plan with the central office equipment specifications and to a certain extent he is able

Paper 56-645, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 26, 1956; made available for printing April 17, 1956.

S. J. Lanigan and T. J. McDonough are with the Rural Electrification Administration, Washington, D. C.

to use digit absorbing to reduce the cost of the equipment. An obvious saving is to use it to avoid completely an additional rank of selectors. A more subtle device is to use it to by-pass a rank of selectors. As an example, an incoming toll selector is normally not equipped with digit absorbing. If it happens to be in an office consisting of, say, one or two groups of terminal per line (TPL) connectors and of, say, four or five groups of terminal per station (TPS) connectors, and if the fourth from the last digit of the TPS numbers could be absorbed, the TPS trunk traffic could be routed to connectors off the incoming toll selectors rather than through the local second selectors with a consequent saving in selectors. In some cases the number of levels required for toll, EAS, and local use exceeds ten, the capacity of the switch, so that the engineer is faced with routing either the local traffic or some or all of the EAS traffic through a second rank of selectors. To the extent which is practical, the group with the least traffic should be routed through the extra rank of selectors, because the number of local first selectors will be the same under either plan, but the number of second selectors will depend on the amount of traffic they are to handle.

All connectors (including TPS) are combination toll and local and each is capable of ringing from one to ten (eight for superimposed ringing) parties on the same party line, provided of course all ten parties have been assigned to the same connector group. Normally there will be only one PBX hunting (rotary) group furnished. In large offices lines equipped with lockout may sometimes be segregated at the linefinder end when it is desirable to avoid having all linefinder groups equipped for lockout, and lines may be segregated at the connector when it is determined some should be operated on a TPL basis and the balance of the lines are to be TPS.

Traffic Estimates

In order to determine more accurately the quantity of inter- and intraoffice trunk circuits required, estimates are based on measurements made at such times as to indicate the hourly traffic which may occur with reasonable frequency. The intentions are to provide equipment which will be used occasionally all during the engineered period and efficiently during the busy season just before the next addition. As a practical matter, whether or not this can be realized will depend on local conditions. Considering the difficulty and the cost of gathering data from unattended dial offices, it is recommended that the traffic measurements be taken during the busy season which covers the three or four consecutive weeks when the circuits are busier than at any other similar period. Generally, all of the circuits in the central office will have the same busy season. In the following discussion, this is assumed to be so. If it is not, adjustments for certain trunk groups can be made based on the measured data, in lieu of a switch count at some other time. It is recommended that all traffic registers be read at the same hour of the same day of each of four consecutive weeks during the busy season prior to a conversion or addition. A thorough traffic study should be made during one of these weeks during which switch counts should be taken on the five business days, normally Monday through Friday. Weeks in which there are holidays are avoided. During the switch count week all traffic meters should be read at approximately the same time each day, preferably the first thing each morning. Measurements should be taken during the busiest hour of each of the five business days. One of the several methods of making switch counts, i.e., physical observations, pen recorder, or automatic trunk usage equipment, should be used on each trunk group to be measured. The observation period should be sufficiently long to insure that the busiest hour of the day will be included. In addition to the weekly and daily reading of the traffic registers, they should also be read at the beginning and end of the busy hour. While there is some stability in trunk groups of ten or more trunks, even here it is a mistake to presume that the hour found busiest on the first day will be the busy hour on succeeding days. With groups of two or three trunks errors of more than 100% of the first day's busy hour readings have been observed. The reason for recording the traffic register readings is twofold: first, to highlight trouble conditions which could cause false indications of usage; and second, to provide a means for averaging the 5 days' busy hour data over the three highest weeks of the busy season. Most of the central offices furnished to REA specification have peg-count meters on connector groups only. It is recommended that all traffic in the office be presumed to be proportional to the connector peg count. A check of the reasonableness of this assumption can be made by comparing the busy hour data for the 5 days in which counts were made. Of course, if peg-count meters are furnished for other trunk groups, the results will probably be more reliable if the usage of these trunk groups are presumed proportional to the associated peg-count meter rather than to the connector peg count. Note that the usage registers (ATB, LTB, and OF) are not directly proportional to usage but they serve as a check of the result. The ratio of the busy hour registrations to the week's registrations during the week in which the switch counts were made should be satisfactory for checking the busy hour estimate for the other 3 weeks in the busy season. The results of this study should then be used as a basis for estimating future requirements.

In manual offices and attended dial offices it might very well be as economical to take switch (or cord) counts during the busy hour of 2 or 3 days in each week of the busy season as it was to obtain the foregoing data for the unattended dial office.

In some situations, a manual switch (or cord) count is the most economical method of getting the usage data from an existing office. When a complete study of the office, rather than just one or two trunk groups, is to be made, the manual switch-count method is less satisfactory. In rural communities, the busy hours of interoffice and intraoffice trunk groups often are not the same, which means that switch counts may have to be taken at various times during the day for different trunk groups. In some cases this may be quite satisfactory but usually it is not.

Pen recorders with from 1 to 20 pens each have been used to study traffic for longer periods of time. When the circuit associated with an individual pen becomes busy the pen moves about 1/8 inch. A pattern is traced in ink on a moving paper tape 103 feet long which is calibrated and synchronized. While this instrument can be made to run the tape at various speeds, it seems best to operate it at 1 foot per hour which means that if it is started at 8 a.m. Monday, it will run until Friday afternoon, which for the vast majority of offices will include the busy hours for five business days. This instrument gives an excellent record which makes it possible to discount circuits which it may indicate were in trouble during test. Each recorder can monitor from 1 to 20 circuits in one or more trunk groups. The fact that detailed information is available for the individual trunk circuit makes it especially useful in correcting difficult problems in graded multiple. One objection to its use is that it takes considerable time to analyze the data satisfactorily.

Another instrument similar to those available commercially but designed and built by REA has been found very useful in traffic measurements. It uses a 10-bank 25-point rotary switch and 11 traffic registers. One register is associated with the wiper of each bank of the switch and the 11th indicates the number of observations made during the study period. One observation is made per minute. This instrument is capable of studying from one to ten groups of trunks with from 1 to 25 trunks in a group. It has one of the limitations of the manual switch-count method in that the meters require reading once or twice an hour at about the time of the busy hour, although it operates unattended at other times. To make this instrument even more valuable, a 16-millimeter black-and-white motion picture camera automatically takes a picture of all meters every 30 minutes. With this extra equipment this instrument can also be set up early Monday morning and taken down Friday evening, making it especially useful for unattended dial offices.

If either the pen recorder or the automatic traffic measuring set is operated unattended, it will not be practical to get traffic register readings during the busy hour but it will still be possible to compare traffic during the 4 weeks on the basis of the weekly registrations.

In many instances there are no historical data to help establish the busy season. It is recommended that at least during the first year of dial operation traffic registers be read and recorded each time an unattended office is visited. This should insure a set of readings for each month of the year. It is also recommended that each year during the busy season some time be spent in the analysis of traffic register readings. An annual switch count does not seem justified except when there is a likelihood of an addition or conversion being required.

REA's central office equipment specification requires that the following registers be furnished, and in offices over 600 lines the registers are to be grouped in one location:

Connector peg count

Connector overflow (OF), last trunk busy (LTB), or an all trunks busy with 6-second timing (ATB-6")

Trunk OF, or ATB-6", on all nongraded trunk groups including intraoffice trunks

Trunk OF or LTB on all graded trunk groups including intraoffice trunks

The REA has recently completed tables which are a modification of the widely used truck adjustment tables. They give the anticipated number of registrations for the various trunk groups under the estimated load. One of the shortcomings of the tables is that except for the timed ATB table the average holding time must be known. Except for connectors no other trunk group is equipped with peg-count registers so it is not convenient to estimate holding time. The borrowers are cautioned that the number of registrations in the table are to be used only as an indicator that there may be an overload, or for that matter an underload. Except for the timed ATB registers the number of anticipated registrations is inversely proportional to the average holding time. Since the initial installation is engineered for a 3-year period, it is likely that shortly after cutover the traffic usage meters on small trunk groups will not be registering even during the busy hour. Even though it is recognized that the ratio may change as the trunk group approaches full load, it is recommended that as soon as practical the borrower determined the ratio of the monthly, weekly, and daily registrations to the busy hour. Many of the small dial offices will be visited only two or three times a month so such ratios will be of value. The REA has tried to impress on the borrowers the fact that the absolute number of registrations is not in itself indicative of the service offered. The grade of service desired, the average holding time, and the number of trunks in the group all help determine the number of registrations. When the registers indicate an apparent overload it is recommended that one of the three methods of measuring usage discussed previously be used.

In some cases existing toll traffic is to be converted into EAS traffic. Such traffic is not measurable ordinarily. The recommended way of estimating it is to determine from traffic records the average number of toll messages per busy hour per main station. Adjustments will probably be required if there is to be a sizable growth in the number of subscribers, especially if a few individuals or firms make a large number of calls. The elimination of the toll charge and improved service will cause a stimulation in calling. The amount of the increase depends somewhat on such items as the distance, toll charge, county seat, schools, shopping, and hospitals. To a certain extent the average holding time depends on these factors also. Adjustments similar to these will also be required to estimate toll traffic when extended area service is added or discontinued.

Where existing manual service is not satisfactory due to overloaded party lines, poor transmission, or insufficient central office equipment or personnel, traffic measurement will probably not be worth taking. When experience with similar offices in the area is not available, the following estimates of originating traffic will usually give satisfactory results:

1-party business	1.5 unit calls (CCS)
1-party residence	1.0
2-party business	1.2
2-party residence	0.8
4-party station	0.6
Multiparty station	0.4–0.5
Pay station	1.5
PBX trunks	4.0

Recent Changes

Until recently the vast majority of the interoffice trunk circuits were 2-way, even in groups of 20 to 25. Beyond this there would usually be two groups of 1-way trunks. REA recently began promotion of combinations of 1-way trunks as first choice and 2-way trunks as last choice in groups of from 11 to 35 trunks. Apparently they were not being specified in the past for two major reasons. First, on new installations the prediction as to how the traffic is going to split is a difficult one so that one large group of 2-way trunks is insurance against a bad estimate. Second, there was no specific recommendation as to how to use the tables for combination groups. Combination trunk groups to be engineered as a graded group with one or more legs of the grade in each central office are now being advised. The 2-way trunks are made last choice in both offices and the 1-way trunks become the first choice trunks. As an example of the type of saving being contemplated, consider a situation in which in the past 25 2-way trunk circuits and 25 incoming selectors would have been required. Under the new plan only ten 1-way, and five 2-way trunk repeaters and 15 incoming selectors would be required in each office if loop dialing circuits had been specified. If some other signaling method had been used, ten additional incoming trunk circuits would have been required in each office.

The following grading principles have been emphasized:

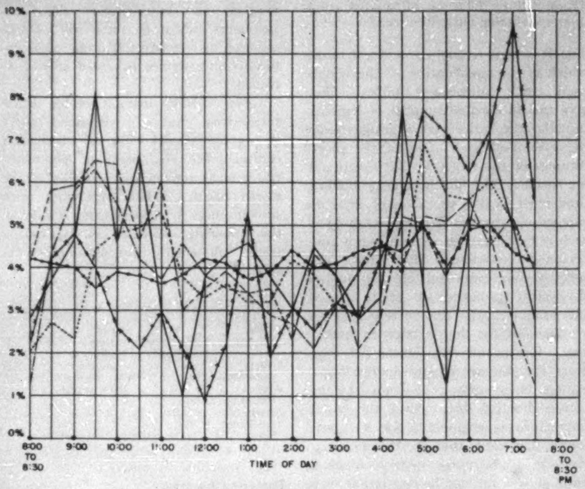

Fig. 1. Traffic on linefinders (hourly variation)

1. The number of trunks common to each leg of the grade should be equal to or greater than one half of the access. Normally there is 10-point access in which case there should be a minimum of five trunks common.

2. As nearly as practical, each leg of the grade should offer the same amount of traffic. This objective can sometimes be met by having more than one shelf of selectors in a leg of the grade.

3. In general, the more legs of the grade (up to about seven or eight) there are, the more efficient the grade. The number of legs in a particular subgroup depends somewhat on the number of shelves and also whether a balanced load is offered by each shelf. Usually an even number of legs in the grade is desirable so that a reversal in the common group in the middle of the grade will better utilize the equipment.

The following formula gives the number of trunks individual to each leg. Fractional trunks in this formula indicate that some trunks must be shared with one or more other legs:

$$\frac{\text{Number of trunks—access}}{\text{Number of legs—1}} = \text{Number of individual trunks}$$

In the case of the 25 trunks referred to previously, assume they are connecting step-by-step offices with approximately equal traffic in each direction (study only even number of legs).

$$\frac{25-10}{4-1}=5 \qquad \frac{25-10}{6-1}=3$$

One leg in each office was not checked because there were more than 15 trunks to be graded. Two legs of the grade in each office is satisfactory. With three legs in each office one additional selector (and possibly trunk circuit) would be required although the group would be more efficient.

Another reason for placing more emphasis on grading at this time is because the number of offices in the REA program of 1,000 lines or more is increasing steadily. Even though the suppliers are presently engineering the grading, an understanding of the technique and the principles is required in order for the engineer satisfactorily to perform acceptance tests. Almost as important as getting an acceptable grading pattern is getting one from which it is easy to grow. It normally would not be desirable to have one that required a major revision when one or two trunks were added.

In some instances, traffic tables which assumed full availability were used in determining the number of trunks in graded groups. To avoid this, the interoffice trunk table was modified so that it is now ungraded up to ten trunks and graded beyond ten. Also, a recommendation that was frequently forgotten is that when there are more than ten trunks in an extended area service group, a grade of service of $P = 0.05$ (rather than $P = 0.10$) should be used even though the distance might be greater than 8 miles. With this in mind, no reference is now made to $P = 0.10$ for groups of 11 or more trunks.

A requirement has recently been added to the central office specification that all intraoffice trunk groups have usage registers installed. There had been instances

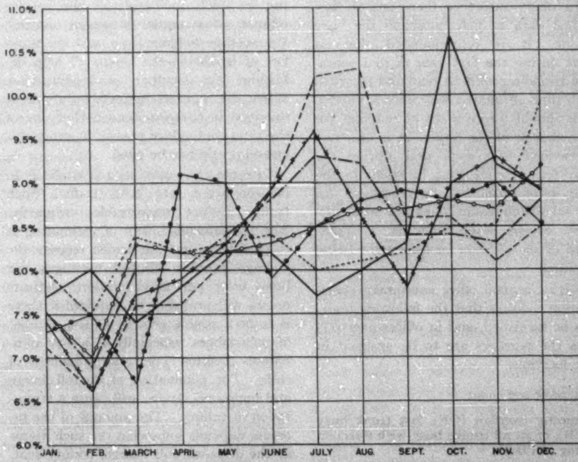

Fig. 2. Traffic on linefinders (monthly variation)

of complaints from subscribers before traffic registers gave an indication of trouble, but this is less likely to happen when intermediate selectors are metered. In one case it was not necessary to reinforce a trunk group when it was found the overload was in a small group of second selectors. Such troubles may be overlooked even by someone trying to do a good traffic study if there are no meters to flag the problem.

It is important that the engineers exercise good judgment, especially in traffic studies. In the design of REA systems, very frequently the individual who makes the commercial survey makes the measurements, prepares the traffic estimate, designs the outside plant, and prepares the central office equipment specification. Such an individual is in a position to prevent optimism or pessimism from being compounded. He can and should make adjustments to give the best over-all design. As an example, some carrier equipment comes in subgroups of four channels each. The fourth channel in the group is relatively inexpensive. The first channel in the next group is quite expensive because of equipment common to four channels. The number of trunks to be installed initially should be determined by such facts rather than by the result of multiplying a certain number of unit calls per station by the number of stations estimated 3 years after cutover. If the engineer knows that there are ample cable pairs, it is possible to give improved service for the same central office cost. In going from, say ten 2-way to seven 2-way, three 1-way incoming, and three 1-way outgoing trunks, there will be a saving (if any change) in central office equipment cost. In many systems the probability of continued growth is great but there are some where growth is not likely. It is important that the designer have this in mind when making borderline decisions.

Results of Traffic Studies on New Installations

The REA has made detail traffic studies in more than 50 central offices. Most of the data compiled so far have been done with the 20 pen recorders. Some examples of the distribution of traffic have been included. Fig. 1 shows how the local originating traffic (unit calls) in six different central offices varies during the day. Fig. 2 shows how the local originating traffic (overflow registrations) in seven different central offices varies each month during the year. Notice that in some offices the busy season extends over several months while in others there is a severe peak.

Based on these studies, the average originating traffic runs from about 0.5 unit calls per station in the small rural offices with little or no EAS traffic to 1.5 unit calls per station in offices with EAS to large metropolitan areas. Of this originating traffic, 20 to 50% will be outgoing EAS and 5 to 25% outgoing toll. The highest EAS and lowest toll rates usually go together and to a lesser degree the reverse is true. It no longer seems strange to have an averaging originating traffic of three unit calls per line, although a few years ago it was almost unheard of in REA designs.

An REA questionnaire requesting that the borrowers tabulate and furnish monthly readings of the traffic registers for the previous 12 months did not have as good a response as was hoped; 23 companies operating 57 exchanges replied. An analysis of the results did not develop facts which would warrant change in basic recommendations. For the most part, those individuals who replied understood their traffic problem and would include footnotes explaining an unusual number of registrations. When overloads were obvious, plans had already been made to provide relief.

Looking Ahead

It is probable that in the next year or two sufficient data can be compiled so that a pattern of regional differences might be determined. Such information may even become more reliable than traffic estimates for dial switchboards based on studies of traffic on manual switchboards. It is not felt that such averages would be suitable for engineering additions to dial offices. Instead actual traffic studies will be required for some time to come. At about the time well-tested traffic estimates can be used in lieu of traffic measurements on manual switchboards, the consulting engineers will probably have become accustomed to and proficient in taking traffic measurements so that the need will be much less than at present.

Some of REA's future efforts will be spent in demonstrating to the borrowers the value of traffic information as a management tool. As more and more of the projects outgrow the initial installation, management becomes increasingly aware of the need for traffic data

The Rural Electrification Administration will continue to evaluate its standards in the light of changing conditions and it is prepared to make adjustments in these standards if it is found they are no longer suitable.

Discussion

Imre Molnar (Automatic Electric Company, Chicago, Ill.): This paper contains much helpful information for traffic engineering of small central offices. It is gratifying to learn that the REA and the authors prefer to base engineering on traffic studies rather than average traffic estimates and feel that traffic usage registers prove in their worth because their results are more tangible. But where such studies are not feasible the table of suggested originating traffic estimates contains valuable information. The plea for good judgment on the part of engineers to prevent optimism or pessimism from being compounded is a particularly sound advice. In traffic engineering the temptation is great to follow the book and be contented when the sliderule produces numerical results; the traffic engineer must translate at each step the numerical result into terms of physical equipment and form a mental picture of the events and reasonableness of results. The suggested methods for traffic estimates are practical and should provide sufficient foundation for engineering community dial office trunking. Perhaps the authors are unaware that there are means available to synchronize peg-count meter readings with automatic traffic recorders.

There are a few details of the paper which appear to require further explanation.

1. It would be interesting to know the considerations governing the grade of service specification, which differs considerably from those in general use. Since the cost of the connector and linefinder (with associated first selectors) ranks are very substantially higher than others, they should stand the greatest amount of the loss when apportioning the total grade of service, instead of the second selectors. This is particularly true for linefinders, where a small increase in delay for dial tone is permissible, particularly when subscribers on multiparty lines

are accustomed to service restrictions on account of sharing the line with many other parties. Likewise, the reverting call switches should be much less liberally provided, because it is usually only preceded by the linefinder delay, and also because once the reverting call switch is reached, the call is subjected no further to line busy.

2. The reason given in the paragraph following the grade of service specification is not clear. If the authors' reasoning is that the probability of finding a multiparty line busy is greater than that of finding a single- or 2-party line busy, and that therefore this situation should not be aggravated by busy-in trunk equipment, it seems that with the usual line-busy rate on multiparty lines even a substantial increase of trunking loss would be relatively small in proportion, and the single- and 2-party subscribers would carry an undue proportion of extra cost in the trunking for the benefit of multiparty subscribers.

3. Why is extended area service trunking less liberal than toll trunking (usually the opposite is recommended)? Is it because toll trunks carry pay-as-you-go revenue traffic (in both directions)? However, the extended area trunking is supposedly paid also by increased monthly rates.

4. What is the distinction between connector overflow, etc., and intraoffice trunk overflow? And why are no registers specified for linefinders?

5. A split between 1-way and 2-way trunks is in many applications a very worth-while feature. However, it must be realized that 20 1-way and 5 2-way trunks are not equivalent to 25 2-way trunks, but that there is always a trunk penalty which must be weighed against the saving in central office equipment, and even more so when there is a difference in the respective trunk busy hours.

6. The authors' request for a grading pattern that is easy to grow from is very sound, but it should also be realized that their grading principles 1 and 3 do not lead to the most efficient grading. Both theory and experience have shown that the most efficient grading can be obtained, first, if the total number of switch outlets in a grading is about twice the number of connecting trunks, and second, if the transition from individuals to commons is as smooth as possible—that is, when it is done in approximately equal number of steps. For instance, if 560 unit calls are offered to a 4-legged grading consisting of four steps of individuals, three steps of pairs, and three steps of quadruples, the overflow is theoretically a little over one half of that obtained by the grading suggested in the paper with 25 trunks, although the latter is easier to administer for growth. In what way is a better utilization of equipment expected by a reversal of the common group? The traffic-carrying capacity cannot be increased by such reversal; only the average number of hunting steps and chance for double connection will be somewhat reduced.

S. J. Lanigan and T. J. McDonough: We appreciate Dr. Molnar's comments, and will try to clarify the questions he has raised.

1. We will probably adopt Dr. Molnar's suggestion of providing connectors and reverting call switches on a less liberal basis. The grades of service for the various ranks of switches deviate only slightly from Bell System practice. Bell System experience with linefinders proved to them that a grade of service as poor as $P = 0.04$ was not acceptable to the public. In unattended dial offices of small companies the administration and maintenance will generally not be as good as in the large attended offices. Load unbalance between subgroups, delay in restoring service, and the fact that many subgroups use 100-point switches influenced us in deciding upon a grade of service after dial tone of $P = 0.03$ for local calls.

2. In most REA systems the rural subscribers make up a majority of the total subscribers. The rates paid for other grades of service depend on the rural residence rate. We would say that the rural residence subscriber is getting the grade of service he requires. The 1-, 2-, or 4-party subscriber may be getting somewhat better service than required.

3. We have been told that on local calls the Bell System tries to maintain a grade of service after dial tone of $P = 0.04$. In multioffice exchanges this means giving a better grade of service on interoffice trunks than we advocate for extended area service. In REA borrower's systems, trunk groups are generally small, and the recommended grades of service are satisfactory. In instances we know of where subscribers have complained, the grades of service have been worse than $P = 0.10$. In addition to the fact that toll traffic is pay-as-you-go, toll trunks handle emergency traffic and the introduction of direct distance dialing also justifies the better grades of service on toll groups.

4. We neglected to state that an OF, ATL, or ATB-6" timing meter is required for each linefinder group. In connection with traffic meters, "intraoffice trunks" refers to second and third selectors and revertive call switches.

5. No comment.

6. We are soon to issue information on engineering central offices larger than 800 lines which will include grading patterns standard in the Bell System for step-by-step offices. The transition from individual to common trunks occurs on the first five contacts, and is not always smooth; however, we plan to follow the Bell System in trying to maintain a minimum of five common trunks in the grade because we expect that a high percentage of graded subgroups will have some unbalance.

Dynamax, a New Crystal and Domain-Oriented Magnetic Core Material

G. H. HOWE
NONMEMBER AIEE

Synopsis: Dynamax, a new high-permeability magnetic material containing approximately 65 per cent (%) nickel, 2% molybdenum, and 33% iron, has been developed in the form of thin tape for toroidal cores. It has dynamic characteristics which are superior to those of any rectangular hysteresis loop materials commercially available today. The most promising potential applications are in high-performance magnetic amplifiers and possibly in special transformers. In addition, its d-c magnetization characteristics are comparable to those of Supermalloy except that the Dynamax has a rectangular hysteresis loop and higher remanance. Dynamax has d-c properties which are superior to Deltamax except for lower saturation.

This development is the result of an alloy modification of 65 permalloy to raise the specific resistance to a useful range and a considerable amount of processing research to produce controlled textures and domain patterns by rolling from specially cast slab ingots, primary recrystallization, pure dry hydrogen annealing, and heat treatment in a magnetic field.

SEVERAL important developments in the field of magnetic materials have come from the nickel-iron system, notably the permalloys. Outstanding from the point of scientific interest were the results reported by Bozorth, Dillinger, and Kelsall[1] on their investigation of the effect of heat-treating a series of nickel-iron alloys in a magnetic field. A large increase in permeability developed, the maximum value occurring in an alloy of about 65% nickel where the Curie temperature is highest in this nickel-iron composition range. Dahl and Pawlek[2] confirmed the large effect of cooling in a magnetic field using 12-mil-thick nickel-iron strips both with random and preferred crystal orientations. Subsequent development of the alloys of this type and the controversy over the mechanism of magnetic annealing have been discussed by Hoselitz.[3]

Fig. 1 (left). Cross section of vacuum-cast Dynamax ingot

Fig. 2 (right). Cross section of $1^1/_2$- by 4-inch Dynamax slab cast in graphite mold

Experimental

The initial work in this investigation was directed at improving the magnetic properties of 65 permalloy by making grain-oriented thin strip for test in wound toroids.

The alloy was vacuum melted in an induction furnace and poured into a cast iron mold. To improve rolling, 0.3% manganese was added. The ingots were reduced to thin strip by hot forging followed by hot and cold rolling.

After slitting to the desired width, the strip was coated with a thin film of hydrated magnesia and wound into toroidal test specimens. Following a 1,100 C (degrees centigrade) preliminary anneal in pure dry hydrogen, the specimens were heated to 650 C in ordinary hydrogen and cooled in a magnetizing field of 10–12 oersteds at 150 C per hour. This treatment is called a magnetic anneal in this paper. It should be noted, however, that it is slow cooling through the Curie temperature in a magnetic field.

The d-c magnetic properties shown in Table I are typical of those obtained on $1^1/_2$-inch inside diameter by $1^7/_8$-inch outside diameter cores wound with 1/2-inch-wide tape of different thickness and heat treated as discussed. It is observed that:

1. Of the 5-mil specimens, nos. *1*, *4*, and *5*, maximum permeability improved with increased percentage of cold reduction.

2. Referring to the second group of specimens, nos. *3*, *5*, and *6*, for a constant amount of cold rolling, $87^1/_2\%$ cold reduction, the magnetic properties were improved by a decrease from 10 mils to 3 mils in finish thickness. The results of X-ray diffraction tests furnished evidence that the degree of preferred crystal orientation also increased with thinner material.

3. The data on specimen *6B* illustrate the effectiveness of the magnetic anneal on this alloy. The maximum permeability is raised by a factor of 125 and the d-c hysteresis loop is squared.

The extreme degree of magnetic softness attained in 65 permalloy was not useful in a-c applications owing to the low (25-michrohm-centimeter) resistivity of the binary alloy. To remedy this serious limitation, molybdenum was first added to 65 permalloy to increase its resistivity as shown in Table II.

While increased resistivity was attained at some sacrifice in d-c magnetic properties, reasonably high maximum permeability and low coercive force were measured on 2-mil by 1/2-inch-wide tape from *VH 466* containing 2.16% molybdenum, i. e.: specimen *466-4*—338,000 maximum permeability, 11,740 B_r, 0.029 H_c, 47.7 microhm-centimeter. The dynamic hysteresis loop of this specimen at 60 and 400 cycles was found to be narrower than that of Deltamax and 65 permalloy. The 3% material was no better dynamically and had a lower saturation density.

In addition to 60- and 400-cycle dynamic hysteresis loops, specimen *466-4* was tested in a half-wave self-saturated magnetic amplifier circuit and control characteristic curves made at 60 and 400 cycles. The results showed a marked superiority in relation to comparable data on Deltamax cores except that the available power output range of the Dynamax core was only 75% that of the Deltamax core. This difference is attributed to the lower saturation density of Dynamax.

Molybdenum was chosen as the alloying material for the following reasons:

1. It was known to raise resistivity more effectively than silicon for a given reduction in saturation density.

2. Its addition to 79 permalloy had produced Supermalloy whose dynamic properties were excellent.

3. It might provide a means for easy nucleation of the domains and thereby improve the dynamic properties.

Metallurgical Development

The development of good magnetic quality in Dynamax parallels that of producing other grain-oriented alloys in that variations in melting, casting, and hot working are reflected in the quality of finished strip.

Early in this investigation ingots of square cross section were reduced to billets by hot forging and further to strip by hot and cold rolling. Good magnetic properties could not be reproduced consistently, so attention was focused on the structure of the ingots. A typical structure of the cross section of these ingots is shown in Fig. 1.

Table I. D-C Magnetic Properties of 65 Permalloy

Heat	Specimen No.	Thickness, Mils	% Cold Reduction	Normal Induction		Hysteresis, Peak H = 12			X-Ray Diffraction
				Maximum Permeability	At B	Peak B	B_r	H_c

Paper 56-681, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted September 7, 1955; made available for printing April 27, 1956.

G. H. Howe is with the General Electric Company, Schenectady, N. Y.

Grateful acknowledgment is made to W. R. Hibbard, Jr., for his support and advice in this work and to H. W. Lord for his invaluable assistance in evaluating the dynamic properties of the magnetic toroidal core specimens.

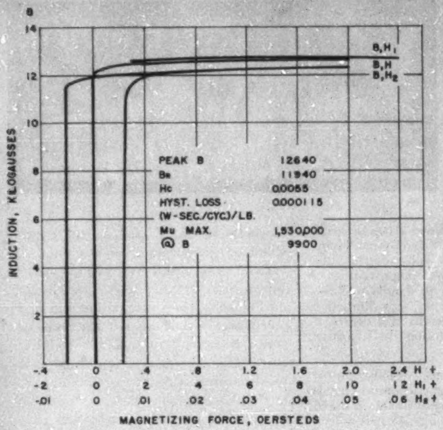

Fig. 3. D-c hysteresis loop Dynamax 2-mil by 1/2-inch tape specimen no. 3B3

It was conceivable that an important variable lay in converting this columnar-cast structure into a uniformly optimum-wrought structure through progressive working under the locally applied forces of a forging hammer. Therefore, a $1^{1}/_{2}$- by 4- by 12-inch slab was cast in a split graphite mold for reduction solely by rolling.

Fig. 2 shows a typical cross section. The ingots being cast vertically, the columnar grains grew from all four sides with most of them perpendicular to the rolling plane.

Table II. Effect of Adding Molybdenum to 65 Permalloy

Material	Molybdenum by Analysis, %	Specimen Resistivity	Specimen Gr.	Curie Temperature, C
VH 465	1	34	8.49	
VH 466	2.16	47.7	8.52	560
VH 561	2.9	54.1	8.63	540

The d-c magnetic properties shown in Table III were obtained on $1^{1}/_{2}$-inch inside diameter by $1^{7}/_{8}$-inch outside diameter cores wound with 2-mil by 1/2-inch-wide tape produced by rolling a portion of the completely columnar slab ingot.

In a previous experiment it was learned that a primary recrystallization treatment improved the magnetic quality. Table III, column 1, shows the effect of this treatment at various temperatures. It is observed that highest permeabilities were measured on tape which had been subjected to recrystallization at 700 C prior to the 4-hour high-temperature anneal and the magnetic anneal.

Reannealing for 4 hours at 1,200 C plus magnetic anneal substantially increased the permeabilities of the prior recrystallized specimens, particularly no. *3B2* which attained 1,615,000 maximum permeability. The poorer properties of no. *3B1* and no. *3B2* after reannealing at 1,300 C can be explained by a difference in crystalline texture.

Table III. Effect of Annealing Treatment on D-C Magnetic Properties of Dynamax

No.	Initial Recrystallization	Maximum Permeability	at B	Peak B	B_r	H_c
	4 Hours at 1,100 C Pure Dry Hydrogen + Magnetic Anneal					
3B1	10 min 500 C	800,000	9,200	12,440	11,490	0.0125
2	10 min 700 C	1,073,000	10,400	12,490	11,910	0.0096
3	10 min 900 C	1,036,000	10,200	12,590	11,980	0.0095
4	None	621,000	8,800	12,740	11,780	0.0150
	4 Hours 1,200 C Reanneal Pure Dry Hydrogen + Magnetic Anneal					
3B1	10 min 500 C	1,231,000	9,300	12,500	11,600	0.0077
2	10 min 700 C	1,615,000	10,100	12,640	12,020	0.0055
3	10 min 900 C	1,530,000	9,900	12,640	11,940	0.0055
4	None	732,000	9,500	12,630	11,880	0.0109
	4 Hours 1,300 C Reanneal Pure Dry Hydrogen + Magnetic Anneal					
3*B*1	10 min 500 C	449,000	8,900	11,090	10,280	0.0176
2	10 min 700 C	551,000	9,500	11,190	10,600	0.0124

Specimen *3B3* measured 1,530,000 maximum permeability after the 4-hour 1,200 C pure dry hydrogen plus magnetic anneals. The d-c hysteresis loop of this specimen is shown in Fig. 3.

The best values which have been attained are 1,780,000 maximum permeability, 11,950 residual flux density, and 0.0053 coercive force. This maximum permeability is higher than any published values the author has seen.

Dynamic Properties

The improvements in dynamic properties obtained by the addition of 2% molybdenum to 65 permalloy cannot be accounted for by the increased resistivity alone. This leads to the belief that the addition of molybdenum brings about a condition in the material which is more favorable to domain nucleation. Because it is believed that imperfections in the magnetic structure of a material are likely spots to form regions of reversed magnetization (i. e., reversal nuclei) it is not unreasonable to assume that the addition of molybdenum may affect the number and distribution of such reversal nuclei.

However, the static and dynamic hysteresis loops recorded by the U. S. Signal Corps on two specimens of Dynamax which had been processed differently indicate that there are processing effects which influence domain size and therefore affect the dynamic loop width. The specimen having the superior d-c properties of low H_c and high ratio of B_r to B_s was inferior dynamically to the specimen having the poor d-c properties. It is apparent that as of now there is no good explanation for this. The answer is expected from further studies of this and similar alloys in search for rectangular core materials having improved dynamic properties.

Dynamax promises to be less sensitive to the effects of temperature variations than are the nickel-iron alloys now commercially available. The effect of core temperature up to 315 C upon the gain of a high-performance magnetic amplifier is about the same for Dynamax as it is for grain-oriented silicon strip cores.

Discussion

Martin F. Littmann (Research Laboratories, Armco Steel Corporation, Middletown, Ohio): The remarkable properties of Dynamax are largely due to the response of this alloy to the magnetic anneal. By contrast, the regular 48% nickel-iron alloys do not respond readily to a magnetic anneal but values of d-c coercive force of 0.02 to 0.03 oersted together with a B_r/B_m ratio above 0.90 at $H_m = 10$ oersteds are obtainable after annealing at 1,100 C without magnetic annealing.

We note with interest the statement that "the improvements in dynamic properties obtained by the addition of 2% molybdenum cannot be accounted for by the increased resistivity alone." However, no dynamic data are shown for the specimens described in the paper. It would be instructive to compare d-c and dynamic data for specimens of varying d-c properties both with and without the molybdenum addition.

The observation that the Dynamax specimen with a high ratio of B_r to B_s was inferior dynamically to the specimen with poor d-c properties confirms the findings of Ward and Littmann[1] that improved squareness of the hysteresis loop increases the width of the dynamic loop even for the same d-c coercive force.

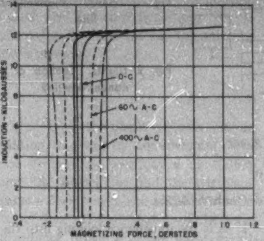

Fig. 4. Hysteresis loops of 2-mil 65 permalloy.

G. H. Howe: I wish to thank Mr. Littmann for his comments.

Communication with Mr. Littmann has revealed he does not wish to imply that the unusually low values of d-c coercive force, i.e. 0.02 to 0.03 oersted for 48% nickel-iron alloys, are obtainable on all heats. Only certain heats had responded so as to produce this extremely low coercive force and still maintain good rectangularity.

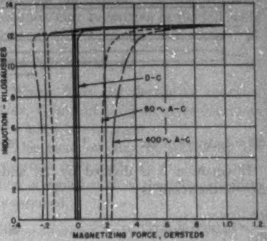

Fig. 5. Hysteresis loops of 2-mil Dynamax

An example of the superiority of Dynamax containing 2% molybdenum over 65 permalloy without the molybdenum addition is furnished in Figs. 4 and 5 which show hysteresis loops for 65 permalloy and Dynamax, respectively. By comparison of the dynamic loops it is observed that the coercive force of the Dynamax is about the same at 400 cycles as that of 65 permalloy at 60 cycles and the Dynamax first quadrant is more rectangular.

Computation of the Impedances of Nonuniform Lines by a Direct Method

LOUIS A. PIPES
MEMBER AIEE

Synopsis: The impedances of nonuniform or tapered lines are computed directly by solving a first-order nonlinear differential equation of the Riccati type. Special cases which include the uniform line, the exponential line, the Bessel line, and the Heaviside-Bessel line are discussed. A general reversion method for solving the nonlinear differential equation for the line impedance is discussed.

TRANSMISSION LINES whose impedance per unit length $Z_L(x)$ and admittance per unit length $Y_L(x)$ vary continuously with the distance x along the line are frequently used in communication engineering. These lines are used to couple circuits that have different impedances in order to avoid abrupt discontinuities. Such nonuniform lines are used in duplex working submarine cables and as circuit elements that have transformer properties.

Several general mathematical analyses of lines of this type have been published.[1–7] The starting points of these analyses are the differential equations for the propagation of currents and potentials of these lines. The solutions are obtained in series form or are expressed in terms of Bessel functions. In certain classes of problems that arise in practice the information concerning the complete distribution of current and potential along the nonuniform line is not required but only a knowledge of the impedance of the line is needed. It is the purpose of this paper to show the line impedance may be obtained by integrating a nonlinear differential equation of the first order of the Riccati type.

The Differential Equation for the Line Impedance

Consider the nonuniform line shown in Fig. 1. Let $Z_L(x)$ be the impedance and $Y_L(x)$ the admittance per unit length of the line. Let Z_r be a lumped impedance connected across the terminals of the line at $x=0$. Let a section of the line of length Δx be represented by Fig. 2.

Let $Z+\Delta Z$ be the impedance across the points A and B of the elementary section of the line of Fig. 2. Z is the impedance across the line at a point x from the receiving end of the line at $x=0$. By the use of the ordinary laws of combination of impedances in series and parallel the following value is obtained for the impedance between the points A and B:

$$Z_{AB} = Z + \Delta Z = Z_L\Delta x + \cfrac{1}{Y_L\Delta x + \cfrac{1}{Z}} = Z_L\Delta x + \frac{Z}{1+Y_LZ\Delta x} \qquad (1)$$

If quantities of order Δx^2 and higher are neglected, the following approximation may be made:

$$\frac{1}{1+Y_LZ\Delta x} = 1 - Y_LZ\Delta x \qquad (2)$$

Therefore equation 1 may be written in the form

Paper 56-685, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted January 19, 1956; made available for printing April 27, 1956.

Louis A. Pipes is with the University of California, Los Angeles, Calif, and the U. S. Naval Ordnance Test Station, China Lake, Calif.

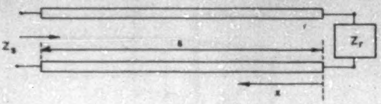

Fig. 1 (left). Nonuniform line

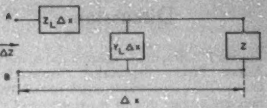

Fig. 2 (right). Section of a nonuniform line

$$\Delta Z = Z_L \Delta x - Y_L Z^2 \Delta x \tag{3}$$

If equation 3 is divided by Δx and $\Delta x \rightarrow 0$, the result is

$$\frac{dZ}{dx} = Z_L(x) - Y_L(x) Z^2 \tag{4}$$

Equation 4 is a first-order nonlinear differential equation of the Riccati type.[8,9] This equation may be transformed into a linear equation of the second order by the following transformation:

$$Z = \frac{1}{Y_L u} \frac{du}{dx} \tag{5}$$

If this transformation is applied to equation 4, the following linear equation in u is obtained:

$$\frac{d^2u}{dx^2} - (Y_L'/Y_L)\frac{du}{dx} - (Z_L Y_L) u = 0 \tag{6}$$

The solutions of the differential equations 4 or 6 will now be obtained for special cases of the variation of $Z_L(x)$ and $Y_L(x)$.

The Uniform Line

If the line is uniform, the impedance $Z_L(x)$ and the admittance $Y_L(x)$ are both constant and have the form

$$Z_L(x) = Z_0 \tag{7}$$

$$Y_L(x) = Y_0 \tag{8}$$

where Z_0 and Y_0 are the constant impedance and admittance per length of the uniform line. In this case, equation 4 may be written in the form

$$\frac{dZ}{(Z_0 - Y_0 Z^2)} = dx \tag{9}$$

and the variables are separated. The integral of equation 9 may be written in the form,

$$Z(x) = Z_c \tanh(ax + \phi) \tag{10}$$

where Z_c is the characteristic impedance of the uniform line and a is the propagation constant of the line. These quantities are defined by the equations

$$Z_c = (Z_0/Y_0)^{1/2} \tag{11}$$

$$a = (Z_0 Y_0)^{1/2} \tag{12}$$

where ϕ is an arbitrary constant. If the line is terminated as shown in Fig. 1, $Z = Z_r$ is at $x = 0$ so that equation 10 gives the result

$$Z_r = Z_c \tanh(\phi) \tag{13}$$

or

$$\phi = \tanh^{-1}(Z_r/Z_c) \tag{14}$$

If Z_s is the impedance looking into the line at $x = s$, then, as a consequence of equation 10,

$$Z_s = Z_c \tanh(\theta + \phi) = [Z_c \tanh(\theta) + Z_r] / [1 + (Z_r/Z_c)\tanh(\theta)] \tag{15}$$

where $\theta =$ as is the angle of the line. This is the well-known result for the impedance of a uniform line of length s terminated by an impedance Z_r. The fact that the impedance of a very long line is Z_c may be seen from equation 10 by allowing x to take a very large value. If this is done, then,

$$\lim_{x\to\infty} Z = \lim_{x\to\infty} Z_c \tanh(ax + \phi) = Z_c \tag{16}$$

Nonuniform Line with $Z_L = Z_0 f(x)$, $Y_L = Y_0 f(x)$

Next to the uniform line, the most simple case to analyze is the one in which the variation of the impedance and admittance per length have the following form,

$$Z_L(x) = Z_0 f(x) \tag{17}$$

$$Y_L(x) = Y_0 f(x) \tag{18}$$

where Z_0 and Y_0 are constants and $f(x)$ is a single-valued continuous function of x. In this case equation 4 may be written in the form,

$$\frac{dZ}{dx} = (Z_0 - Y_0 Z^2) f(x) \tag{19}$$

Hence,

$$\frac{dZ}{(Z_0 - Y_0 Z^2)} = f(x)\,dx \tag{20}$$

If both members of equation 20 are integrated, the result may be written in the form,

$$\frac{1}{a}\tanh^{-1}(Z/Z_c) = \int f(x)\,dx + C \tag{21}$$

where $Z_c = (Z_0/Y_0)^{1/2}$, and C is a constant.

Equation 21 may be written in the alternative form,

$$Z = Z_c \tanh\left[a \int f(x)\,dx + \phi\right] \tag{22}$$

where ϕ is an arbitrary constant to be determined by the termination of the line at $x = 0$. If $f(x) = 1$, the line is uniform and equation 22 reduces to equation 10. Equation 22 may be used to compute the impedance of nonuniform lines for special functions $f(x)$. If, for example, the nonuniform line has a periodic variation of impedance and admittance per unit length of the form,

$$Z_L(x) = Z_0[1 + m\cos(wx)],\ m < 1 \tag{23}$$

$$Y_L(x) = Y_0[1 + m\cos(wx)]$$

then $f(x) = [1 + m\cos(wx)]$ and equation 22 becomes

$$Z = Z_c \tanh\left[x + \frac{m}{w}\sin(wx) + \phi\right] \tag{24}$$

The Exponential Line

A nonuniform line whose performance has been considerably investigated[5,6] is one whose impedance and admittance variations are of the form,

$$Z_L(x) = Z_0 e^{kx} \tag{25}$$

$$Y_L(x) = Y_0 e^{-kx} \tag{26}$$

where Z_0, Y_0, and k are constants. This nonuniform line is called the "exponential line" in the literature. In order to obtain an expression for the impedance of this line, substitute equations 25 and 26 into equation 6 and obtain the following equation,

$$\frac{d^2u}{dx^2} + \frac{k\,du}{dx} - a^2 u = 0,\ a = (Z_0 Y_0)^{1/2} \tag{27}$$

This equation has the solution

$$u = A e^{-kx/2}\cosh(wx + \phi) \tag{28}$$

where

$$w = \left(a^2 + \frac{k^2}{4}\right)^{1/2} \tag{29}$$

and A and ϕ are arbitrary constants. The impedance of the line is given by equation 5 in the form,

$$Z = (1/Y_L u)\frac{du}{dx} = \frac{e^{kx}}{Y_0}[w\tanh(wx + \phi) - k/2] \tag{30}$$

ϕ is an artibrary constant. If the line is terminated at $x = 0$ by an impedance Z_r, then

$$Z_r = \frac{1}{Y_0}[w\tanh(\phi) - k/2] \tag{31}$$

Hence ϕ is determined by the following equation,

$$\tanh(\phi) = \frac{1}{w}[Z_r Y_0 + k/2] \qquad (32)$$

The magnitude of the sending-end impedance of the line Z_s is obtained by placing $x = s$ in equation 30. The result is

$$Z_s = \frac{e^{ks}}{Y_0}[w\tanh(ws+\phi) - k/2] \qquad (33)$$

where ϕ is determined by equation 32. If $k=0$ it can be shown that equation 33 reduces to the case of the uniform line equation 15.

The Case $Y_L = Y_0$, $Z_L = Z_0x^p$

Another special case that admits a relatively simple solution is the one in which the admittance per length Y_L is a constant Y_0 and the impedance per length Z_L varies as a power of x in the form, $Z = Z_0x^p$. In this case, equation 4 takes the form,

$$\frac{dZ}{dx} = Z_0x^p - Y_0Z^2 \qquad (34)$$

Equation 6 is now of the form,

$$\frac{d^2u}{dx^2} - Z_0Y_0x^pu = 0 \qquad (35)$$

The general solution of equation 35 may be written in the form,

$$u = x^{1/2}[AI_n(w) + BI_{-n}(w)] = x^{1/2}F(x) \qquad (36)$$

where

$$w = rx^q$$

$$r = \frac{2(Z_0Y_0)^{1/2}}{(p+2)}$$

$$n = 1/(p+2)$$

$$q = (1+p/2)$$

$I_n(w)$ is the modified Bessel function for the first kind of order n.[10] The impedance Z is given by equation 5 in the following form,

$$Z = (1/Y_Lu)\frac{du}{dx} = \frac{1}{Y_0}\left[1/2x + (1/F)\frac{dF}{dx}\right] \qquad (37)$$

$$= (1/2Y_0x)(1 + 2rqx^q[I_n'(w) + CI_{-n}'(w)]/[I_n(w) + CI_{-n}(w)])$$

where

$$I_n'(w) = \frac{dI_n}{dw}(w) \qquad (38)$$

The arbitrary constant C may be determined from the boundary condition of the line at $x=0$.

The Case $Y_L = Y_0x^a$, $Z_L = Z_0x^b$

The case in which the admittance and impedance per length have the form $Y = Y_0x^a$ and $Z = Z_0x^b$ has been investigated by several writers.[2,4] In general, if $a=b$ the line impedance may be obtained by the nonuniform line method and is given by

$$Z(x) = (Z_0/Y_0)^{1/2}\tanh[x^{a+1}/(a+1)+\phi], \quad a \neq -1 \qquad (39)$$

If $a=b=0$, the line is uniform and the solution is given by equation 10. The case $a=-b$ has been called by Ballantine[2] the Bessel line and the particular case $a=1=-b$ is known as the Heaviside-Bessel line. If $b=1$ and $a=0$ the series impedance tapers and the shunt admittance is constant. The reverse case has also been investigated.

In the general case $Y_L = Y_0x^a$, $Z_L = Z_0x^b$ equation 6 becomes

$$\frac{d^2u}{dx^2} - \frac{a}{x}\frac{du}{dx} - k^2x^{(a+b)} = 0, \quad k = (Z_0Y_0)^{1/2} \qquad (40)$$

The solution of equation 40 may be expressed in the form,

$$u = x^p[AI_n(w) + BK_n(w)], \quad p = (1+a)/2, \quad w = \theta x^q,$$

$$\theta = 2k/(a+b+2), \quad q = 1 + (a+b)/2, \quad n = (1+a)/(a+b+2) \qquad (41)$$

A and B are arbitrary constants and the functions $I_n(w)$ and $K_n(w)$ are modified Bessel functions of the first and second kinds of order n.[11] The line impedance $Z(x)$ may be obtained by means of equation 5 in the form,

$$Z(x) = 1/(Y_Lu)\frac{du}{dx} \qquad (42)$$

where u is given by equation 41 and

$$\frac{du}{dx} = px^{p-1}[AI_n(w) + BK_n(w)] + x^p[AI_n'(w) + BK_n'(w)]\frac{dw}{dx} \qquad (43)$$

If equations 41 and 43 are substituted into equation 42 and certain algebraic reductions are performed, the impedance $Z(x)$ may be expressed in the form,

$$Z(x) = \frac{1}{Y_0}x^a(p/x + \theta qx(p+q-1) [I_n'(w) + CK_n'(w)]/[I_n(w) + CK_n(w)]) \qquad (44)$$

where C is an arbitrary constant which may be determined by the given termination of the line at $x=0$. The primes indicate differentiation of the Bessel functions with respect to their argument w.

Determination of the Line Impedance by the Method of Reversion

In certain cases, the line impedance $Z(x)$ may be obtained approximately by obtaining an approximate solution of the nonlinear differential equation 4. This equation may be written in the following form,

$$DZ + Y_L(x)Z^2 = kZ_L(x) \qquad (45)$$

Where D is the derivative operator d/dx, $Y_L(x)$ and $Z_L(x)$ are given functions of x and k is a constant.

This equation may be solved by the reversion method.[13] To do this, a solution of equation 45 of the following form is assumed,

$$Z(x) = Z_1(x)k + Z_2(x)k^2 + Z_3(x)k^3 + Z_4(x)k^4 + \ldots \qquad (46)$$

The functions $Z_i(x)$ are impedance functions that may be determined by substituting equation 46 into 45 and equating like powers of k in the resulting equation. If this is done, it is found that the $Z_i(x)$ functions satisfy the following differential equations:

$$DZ_1 = Z_L(x) \qquad (47)$$

$$DZ_2 = -Y_LZ_1^2 = f_2(x) \qquad (48)$$

$$DZ_3 = -2Y_LZ_1Z_2 = f_3(x) \qquad (49)$$

$$DZ_4 = Y_L(Z_2^2 + 2Z_1Z_3) = f_4(x) \qquad (50)$$

$$DZ_5 = -2Y_L(Z_1Z_4 + Z_2Z_3) = f_5(x) \qquad (51)$$

$$DZ_6 = -Y_L(Z_3^2 + 2Z_1Z_5 + 2Z_2Z_4) = f_6(x) \qquad (52)$$

$$DZ_7 = 2Y_L(Z_1Z_6 + Z_2Z_5 + Z_3Z_4) = f_7(x) \qquad (53)$$

The equations satisfied by the functions $Z_i(x)$ of higher indexes may be obtained in a similar manner. If the boundary condition $Z = Z_r$ at $x=0$ is used, it can be seen that the integrals of the foregoing differential equations may be expressed in the form,

$$Z_1(x) = Z_r + \int_0^x Z_L(x)dx \qquad (54)$$

$$Z_i(x) = \int_0^x f_i(x)dx, \quad i = 2,3,4,5,\ldots \qquad (55)$$

If the constant $k=1$, it is seen that equation 46 is a formal solution of equation 4 provided the series converges. For example, consider a uniform line so that $Z_L = Z_0$ and $Y_L = Y_0$. Let the line be short-circuited at $x=0$ so that $Z_r = 0$.

In this case,

$$Z_1 = Z_0x \qquad (56)$$

$$Z_2 = -Y_0\int_0^x Z_0^2x^2dx = -Z_0^2Y_0\frac{x^3}{3} \qquad (57)$$

$$Z_3 = 2\int_0^x Y_0Z_0^3Y_0\frac{x^4}{3}dx = \frac{2}{15}Z_0^3Y_0^2x^5 \qquad (58)$$

With $k=1$, the series equations 46 in this case become

$$Z(x) = Z_0x - Z_0^2Y_0\frac{x^3}{3} + \frac{2}{15}Z_0^3Y_0^2x^5 - \ldots \qquad (59)$$

This series may be written in the following form,

$$Z(x)=(Z_0/Y_0)^{1/2}\left[(Z_0Y_0)^{1/2}x-(Z_0Y_0)^{3/2}\frac{x^3}{3}+(Z_0Y_0)^{5/2}\frac{2x^5}{15}-\ldots\right]$$
$$=Z_c\left[(ax)-\frac{(ax)^3}{3}+(ax)^5\frac{0.2}{15}-\ldots\right]$$
$$=Z_c\tanh(ax),\ Z_c=(Z_0/Y_0),^{1/2}a=(Z_0Y_0)^{1/2} \qquad (60)$$

The reversion method is therefore seen to give the series expansion of the impedance of the uniform line. The method is particularly useful if $Z_L(x)$ and $Y_L(x)$ are polynomials in x.

Dynamic Behavior of a 3-Phase Magnetic Amplifier

F. J. ELLERT
ASSOCIATE MEMBER AIEE

IN MANY magnetic-amplifier applications, the transient response of the magnetic amplifier is of considerable importance. This is especially true if the magnetic amplifier is to function as an element of a feedback control system. The object of the work described in this paper was to determine experimentally the dynamic performance of a 3-phase bridge magnetic-amplifier circuit.

Polyphase magnetic-amplifier circuits, as well as single-phase circuits, exhibit both a dead-time lag (transportation lag) T_d and a time constant T_C. Measurements indicate that the polyphase magnetic amplifier also exhibits what appears to be a linear rise during the initial portion of a transient when the control circuit impedance is high. For lack of a better term, this linear rise will be called a ramp function in this paper.

The circuit diagram for the 3-phase bridge magnetic amplifier is shown in Fig. 1. The circuit consists of six identical saturable reactor units; each saturable reactor unit contains a gate winding and multiple-control and bias windings on a silicon iron core. In this investigation, cut C cores of Silectron were used; their dynamic and static hysteresis loops are shown in Fig. 2. The dynamic loop was measured under sinusoidal flux conditions at the supply frequency of 60 cycles per second.

The measured control characteristic of this circuit for the resistive load case is shown in Fig. 3 plotted in normalized form. Curve A shows the useful portion of the control characteristic and curve B (to another scale) shows the upper positive region and the entire negative region of the characteristic in greater detail. In this figure, the base for the per-unit load current i_L is the rated average load current of the circuit. The base for the per-unit magnetizing force H/H_c of the control circuit is the coercive force H_c of the dynamic hysteresis loop as given in Fig. 2.

Nomenclature

Ang = phase angle, radians
B = magnetic flux density, gausses
db = decibels
d_o = oscilloscope deflection which corresponds to the peak load current, millimeters
E_C = control voltage, volts, average
$\bar{E}_C$ = change in control voltage, volts, average
$E_i(p)$ = input voltage as a function of the Heaviside operator p
E_L = load voltage, volts, average
E_O = output voltage (I_LR_O), volts, average
$\bar{E}_O$ = change in output voltage, volts, average
$E_O(p)$ = output voltage as a function of the Heaviside operator p
e_{1-2} = voltage between line 1 and line 2, volts, instantaneous
e_{l-n} = voltage between line and the neutral, volts, instantaneous
$e_{C,A}$ = control voltage on $SR\ A$, volts, instantaneous
$e_{G,A}$ = gate voltage on $SR\ A$, volts, instantaneous
$e_i(t-T_d)$ = input voltage displaced in time by an amount T_d, volts, instantaneous
e_L = load voltage, volts, instantaneous
$e_O(t)$ = output voltage as a function of time, volts, instantaneous
$e_{R,A}$ = rectifier voltage on $REC\ A$, volts, instantaneous
f = supply frequency, cycles per second
H = component of the magnetic intensity produced by the winding, oersteds, instantaneous
$H_c = H$ for zero flux on a symmetrical dynamic hysteresis loop, oersteds, instantaneous
I_C = control current, amperes, average
I_G = gate current, amperes, average
I_L = load current, amperes, average
$\bar{I}_L$ = change in load current, amperes, average
$\bar{I}_{L,M}$ = total change in the average load current between two steady-state levels, amperes, average
i_C = control current, amperes, instantaneous
$i_{G,A}$ = gate current in $SR\ A$, amperes, instantaneous
i_L = per-unit load current
K_{AT} = ampere-turn gain
K_E = voltage gain
L_L = load inductance, henrys
L_m = log modulus (= 20 $\log_{10}$)
l_{Fe} = mean length of the magnetic circuit, centimeters
N_C = number of turns on one control winding
N_G = number of turns on one gate winding
p = Heaviside operator
$R_{B,x}$ = external resistance inserted in the bias circuit, ohms
R_C = resistance of six control windings in series, ohms
$R_{C,x}$ = external resistance inserted in the control circuit, ohms
R_G = resistance of one gate winding, ohms
$R_{G,A}$ = gate resistance of $SR\ A$, ohms

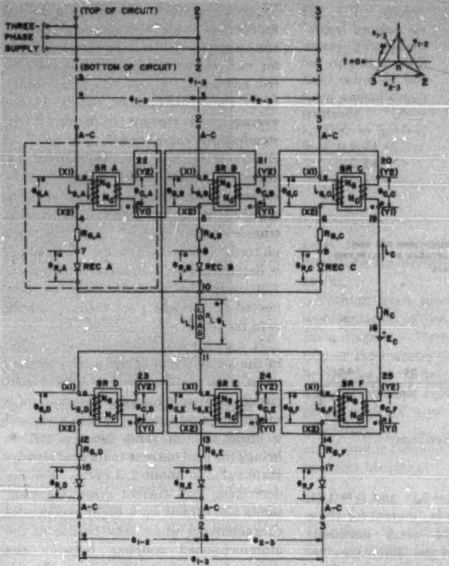

Fig. 1. Three-phase bridge magnetic amplifier circuit

R_L = load resistance, ohms
R_O = total series resistance encountered by the load current, ohms
SR = saturable reactor
T_C = control circuit time constant, seconds
T_d = dead-time lag, seconds
T_ϵ = equivalent time constant of the ramp function, seconds
T_L = load time constant (L_L/R_L), seconds
T_r = duration of the ramp function, seconds
t = time, seconds, or cycles as indicated
ω = angular frequency, radians per second
ϵ = base of natural logarithms (= 2.718 approximately)

Dead-Time Lag

Experimental Procedure

As already mentioned briefly, the response of this magnetic-amplifier circuit to a step of control voltage may consist of a dead-time lag, a ramp function, and an exponential function which is more commonly expressed in terms of a control circuit time constant. To remove the exponential portion of the transient and permit a more detailed measurement of the initial portions of the transient, a large external resistance $R_{C,x}$ was inserted in the control circuit of the magnetic amplifier. Furthermore, to reduce the effects of coupling between the control and bias circuits, a large external resistance $R_{B,x}$ was also inserted into the bias circuit. The arrangement of the control and bias windings is shown in Fig. 4. As indicated in Fig. 4(B), the bias windings are all connected in series. On the other hand, a series-parallel arrangement of windings is employed for the control circuit to permit a substantial reduction in the control circuit time constant without the need of an extremely large external resistance and a high-voltage supply. Additional measurements were also made with the control windings connected in series and without the bias windings.

Transient-response measurements were made by photographing the load current transients on an oscilloscope equipped with a triggered sweep, the triggering signal being obtained from the control circuit as switch S is closed. To ascertain the magnitude of any time constants still present in the circuit, a positive step of control voltage was applied to the control circuit with the bias circuit energized but with the magnetic amplifier disconnected from the a-c supply. Transients of the control current, bias current, and induced voltage in an additional isolated winding on one core were photographed. Both currents exhibited essentially a step function response. The induced voltage, on the other hand, exhibited exponential properties but the entire induced-voltage transient was complete in approximately 1/15 cycle of the supply frequency (60 cycles per second). This indicates a flux time constant of approximately 1/60 cycle.

If a negative step of control voltage is applied to the control circuit, the voltages induced in the gate windings are of such a polarity as to cause currents to circulate in the gate and load circuits. Thus, an effective time constant for the gate and load circuits becomes part of the transient response. This time constant does not enter the transient response to such a great degree when the control voltage step is positive because the voltages induced in the gate windings are prevented from circulating currents by the rectifiers. The effects of such coupling between the control and gate circuits will be described in more detail later.

The transient-response photographs present the instantaneous load current as a function of time. Since the load is resistive, the sixth harmonic ripple is quite predominant in the load current wave shape. In addition, ripple due to core dissymmetries is also evident. However, due to the shape of the dynamic hysteresis loop of the core material, the load current is not discontinuous at any operating point on the control characteristic.

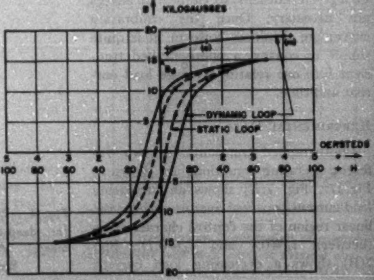

Fig. 2. Dynamic and static hysteresis loops of the magnetic cores

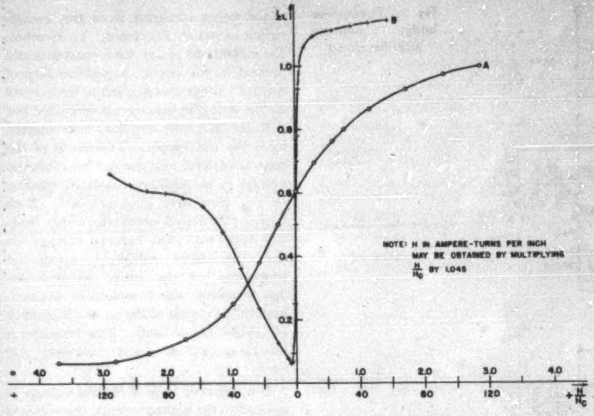

Fig. 3. Measured control characteristic plotted in normalized form

To obtain the transient response of the magnetic amplifier in terms of the average load current, it is necessary to convert the peak current values as seen on the photographed transients into average values by means of a calibration curve. Such a curve is obtained by setting the load current at a desired value and then photographing this steady-state current as displayed on the oscilloscope. When the peak load current is measured in millimeters on each photograph and related to the average load current as measured on a d-c ammeter, the calibration curve results. Two such photographs are shown in Fig. 5 and each photograph results in one point on a calibration curve such as that shown in Fig. 6, where d_o is the height in millimeters of the peak load current on the photograph. Since the peak currents for a given average load current vary from core to core, it is necessary to plot a calibration curve for each core (or each peak). Therefore, for a given transient, six calibration curves are necessary. Once the calibration curves are obtained, however, it is quite simple to convert a photographed transient into one relating average load current and time.

EXPERIMENTAL DATA

Photographed transients for two different operating conditions are shown in Fig. 7. Fig. 7(A) shows an increasing load current transient over essentially the linear region of the control characteristic (between $i_L=0.4$ and $i_L=0.7$). Fig. 7(B) shows a decreasing load current transient between $i_L=0.74$ and $i_L=0.24$. The oscilloscope gain is different for these two transients. The sixth harmonic ripple frequency and the differences between the six cores are quite evident from these photographs. In measuring these transients, the oscilloscope gain was increased to insure reasonable accuracy in the measurement of the load current changes. As a result, the zero level of the current cannot be shown on the oscilloscope screen and is actually far below the area of the screen.

An average load current transient is then obtained by measuring the peak load current at 1/6-cycle intervals on the photographed transient and relating this measurement to the average load current by means of the calibration curves. A number of such average load current transients are shown in Figs. 8 through 12 for various operating regions on the control characteristic. For these transients, I_L is the instantaneous change in the average load current from the initial steady-state value, and $I_{L,m}$ is the total change in the average load current between the initial and final steady-state values. With this notation, both increasing and decreasing load current transients take on the same form when plotted. Since the average load current is determined only at discrete intervals of 1/6 cycle, the plotted points are connected by straight lines merely to indicate the trend.

It appears from these transients that in the linear region of the control characteristic the response with a high control circuit resistance consists essentially of a maximum dead-time lag of 1/6 cycle and a linear rise (or ramp function) which brings the load current to its final steady-state value in about 2/3 cycle. For the decreasing load current cases, the transients also exhibit some slight exponential characteristics which may be due to the aforementioned coupling between the gate and control circuits.

MATHEMATICAL AND GRAPHICAL REPRESENTATION OF THE DEAD-TIME LAG

As in the case of single-phase magnetic-amplifier circuits, the dead-time lag for this 3-phase circuit arises from the sampled nature of the output. For merely the dead-time lag itself, the output $e_O(t)$ is related to the input as follows.

$$e_O(t) = e_i(t - T_d) \tag{1}$$

That is, the output is a perfect replica of

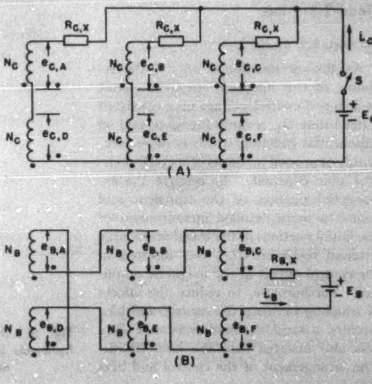

Fig. 4. Winding arrangement for dead-time lag measurements. A—Control circuit. B—Bias circuit

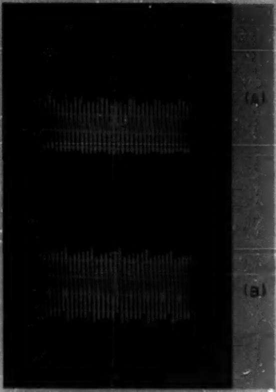

Fig. 5. Typical calibration photographs for transient response measurements. A—I_L = 2.0 amperes. B—I_L = 3.5 amperes

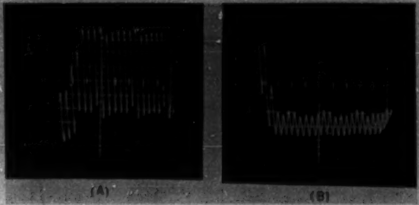

Fig. 7 (right). Typical transient response photographs for operation with high value of external control circuit resistance. A—i_L = 0.4 to i_L = 0.7. B—i_L = 0.74 to i_L = 0.24

the input but is delayed by a fixed amount T_d. The transfer function for a circuit element which produces such a delay is[1,2]

$$\frac{E_O(p)}{E_I(p)} = \epsilon^{-pT_d} = \epsilon^{-j\omega T_d} \qquad (2)$$

where p is the Heaviside operator and T_d is the dead-time lag in seconds.

In the analysis and synthesis of feedback control systems containing magnetic amplifiers, the representation of the dead-time lag in forms other than that of equation 1 becomes necessary. For example, on a Nyquist diagram (complex plane) the dead-time lag is represented by a vector of constant magnitude (unity) whose phase angle increases linearly with frequency. The expression for the phase angle is

$$\text{Ang}\,(\epsilon^{-pT_d}) = -\omega T_d \text{ (radians)} \qquad (3)$$

Therefore, on a Nyquist diagram the locus for the transfer function of the dead-time lag element is a circle of unity radius.

Perhaps even more important is the representation of the dead-time lag on a Bode diagram. Here the magnitude portion of the transfer function is described by the log modulus L_m in decibels (db) and the phase is again described by the phase angle of equation 3.[3] Since the magnitude of the transfer function is unity and is frequency invariant, the log modulus becomes

$$L_m(\epsilon^{-pT_d}) = L_m(1) = 0 \text{ db} \qquad (4)$$

Therefore, to add the transfer function for a dead time lag to the existing transfer function of a system, it is merely necessary to add the phase angle of the dead-time lag as given in equation 3 to the existing phase angle of the system. As indicated in equation 4, no change is necessary in the amplitude portion of the system transfer function. Although the phase angle as given in equation 3 is a linear function of the angular frequency, it will not appear as a straight line on a Bode diagram because of the logarithmic scale which is commonly employed for the angular frequency ω.

Whenever an analogue computer study is made of a system containing a dead-time lag element, it is desirable to represent the transfer function of the dead-time lag element by means of physically realiz-

able circuits. This is, in general, accomplished by approximating the transfer function of equation 2 by a ratio of rational polynomials. This technique will not be discussed in this paper since it is adequately described in the literature.[4,5,6]

Ramp Function

Experimental Data

The transients shown in Figs. 8 through 12 clearly indicate the presence of a somewhat linear rise in the response when a step of control current is applied to the control windings. The few transients shown here are representative of the many transients which were actually measured. It is interesting to note that for the increasing load current transients, the duration of the linear rise is approximately 1/2 cycle of the carrier frequency. Experimentation has shown that the duration of the ramp is not a constant for all operating conditions. If the a-c supply voltage is decreased, resulting in underexcitation of the magnetic amplifier, the duration of the ramp increases. For a-c supply voltages from slightly below nominal voltage to voltages above the nominal value, the duration of the ramp remains essentially constant at the value shown in Figs. 8 through 12. The ramp appears to be caused by an accommodation process in the cores whereby the cyclical core flux adjusts itself from operation on one minor hysteresis loop to another, as dictated by the magnitude of the control current step. The exact nature of the flux adjustment in each core is a function of its operating point on the hysteresis loop at the instant the step is applied. For cores which are saturated at that time no flux adjustment can occur.

Mathematical Representation of the Ramp Function

It is possible by conventional methods to obtain a transfer function for an element which produces a ramp function in response to an applied step function. The expression for the transfer function of such an element is

$$\frac{E_O(p)}{E_i(p)}=\frac{1}{pT_r}(1-\epsilon^{-pT_r}) \qquad (5)$$

where T_r is the duration of the ramp function in seconds. For this 3-phase circuit, the duration of the ramp function is approximately 1/2 cycle of the supply frequency f for increasing load current transients. Therefore, for this case, equation 5 becomes

$$\frac{E_O(p)}{E_i(p)}=\frac{2f}{p}\left(1-\epsilon^{-\frac{p}{2f}}\right) \qquad (6)$$

In some cases, it may be desirable to represent the ramp function by a transfer function which is of necessity simpler and, as a result, less accurate. One possibility is to represent the ramp function by an equivalent single time constant. If the time integral of the instantaneous error between the values of the ramp and the equivalent exponential is to be zero, the relationship between the equivalent time constant T_e and the duration of the ramp T_r is

$$T_e=\frac{T_r}{2} \qquad (7)$$

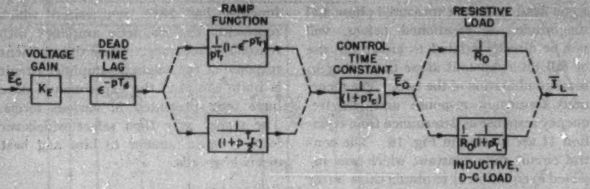

Fig. 15. Block diagram of 3-phase bridge magnetic-amplifier circuit for increasing load current transient

The transfer function for the element producing the ramp then becomes

$$\frac{E_O(p)}{E_i(p)}=\frac{1}{(1+pT_e)}=\frac{1}{\left(1+p\frac{T_r}{2}\right)}. \qquad (8)$$

It should be clear that equation 8 describes only approximately the transient behavior of the ramp.

Time Constant

EXPERIMENTAL PROCEDURE

For low or intermediate values of control circuit resistance, the exponential function becomes the predominant part of the transient response. The evaluation of the control circuit time constant from the measured transients is then quite simple.

For these measurements, the six control windings were connected in series as shown in Fig. 1; the bias windings were not used. No time constant measurements were made with the series-parallel arrangement of control windings shown in Fig. 4(A). The calibration and measurement techniques described in conjunction with the dead-time lag were also followed here. However, in this case, the total control circuit resistance was reasonably small.

EXPERIMENTAL DATA

Two photographs of load current transients over the essentially linear region of the control characteristic are shown in Figs. 13 and 14. Fig. 13 shows an increasing load current and Fig. 14, a decreasing load current. The values of the measured time constants are given below the respective figures. As indicated, the time constant of the decreasing or falling load current is greater due to the coupling between the gate and control circuits. The total time constant in this case is equal to the sum of the control circuit time constant (as given by the rising transient) and an equivalent gate circuit time constant.

MATHEMATICAL REPRESENTATION OF THE TIME CONSTANT

The control circuit time constant T_C, for the case of the series-connected control windings, may be calculated with reasonable accuracy from the following equation

$$T_C=\frac{1}{2f}K_{AT}\frac{R_O}{R_C}\left(\frac{N_C}{N_G}\right)^2 \text{ (seconds)} \qquad (9)$$

where K_{AT} is the ampere-turn gain of the magnetic-amplifier circuit, R_O is the total resistance encountered by the load current, and R_C is the total control circuit resistance. Equation 7 is identical to the expression for the control circuit time constant of a single-phase magnetic amplifier.[7] The measured time constants for increasing load currents were within a few per cent of the values calculated from equation 9 when R_O was corrected to include the effects of the aftersaturation inductance of the gate windings. This is certainly within the required engineering accuracy.

The transfer function for a circuit element which produces an exponential output in response to a step function input is[8]

$$\frac{E_O(p)}{E_i(p)}=\frac{1}{(1+pT)} \qquad (10)$$

where T is the time constant of the exponential expressed in seconds. For an increasing load current transient, T becomes the control circuit time constant T_C; for a decreasing load current transient, T becomes the sum of the gate and control circuit time constants. If a sinusoidal a-c signal is applied to the control circuit of the magnetic amplifier, the response exhibited will result from some combination of the rise and fall time constants. The exact expression for the transfer function under this condition is not known.

Complete Transfer Function

BLOCK DIAGRAM REPRESENTATION

In the analysis and synthesis of feedback control systems, it is quite common to represent each element of the system by a block diagram which relates the input and output of the element by means of a transfer function. In the case of a magnetic amplifier, this transfer function relates the change in output voltage $\overline{E}_O$ to the change in control voltage $\overline{E}_C$.[9] For the resistive load case, the change in output voltage $\overline{E}_O$ is very simply related to the change in load current $\overline{I}_L$ by means of the output resistance R_O. The transfer function of the 3-phase bridge magnetic-amplifier circuit for an increasing load current transient is

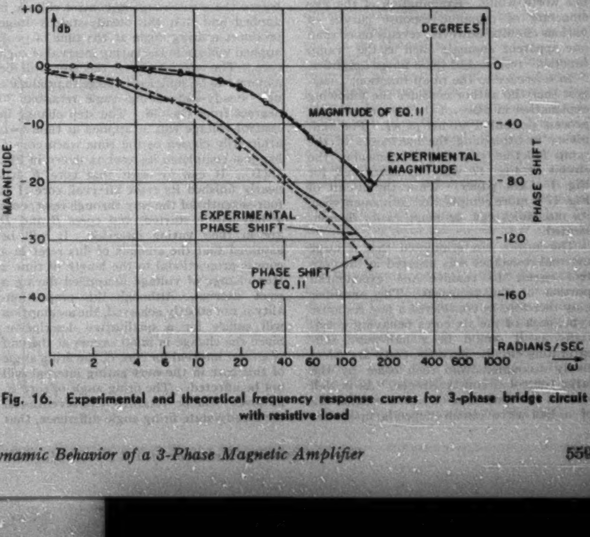

Fig. 16. Experimental and theoretical frequency response curves for 3-phase bridge circuit with resistive load

$$\frac{E_O}{E_C}=K_E\left(\epsilon^{-\frac{p}{6f}}\right)\frac{2f}{p}\left(1-\epsilon^{-\frac{p}{2f}}\right)\frac{1}{(1+pT_C)} \tag{11}$$

where K_E is the voltage gain of the magnetic-amplifier circuit, the assumed dead-time lag T_d is $1/6f$ seconds (1/6 cycle), and the duration of the ramp function is 1/2 cycle. The general block diagram is shown in Fig. 15. The two possible representations of the ramp function are also shown. Depending on the nature of the load, one or the other of the blocks shown at the output must be used to obtain the change in load current. For the inductive, d-c load case, T_L is the load time constant L_L/R_L in seconds.

FREQUENCY RESPONSE MEASUREMENTS

To verify experimentally the transfer function equation 11, the frequency response of the magnetic amplifier was measured by applying a sinusoidal voltage of adjustable frequency to the control circuit and measuring the magnitude and phase of the output voltage. Since the control current under these conditions is sinusoidal and causes positive and negative excursions of the load current about some fixed value, the measured phase and magnitude, as mentioned before, will not be directly related to either the rise or fall time constant alone but rather to some combination of the two. The measured frequency response and the frequency response as determined from equation 11 are plotted in Fig. 16. The control circuit time constant which was inserted in equation 11 to obtain these latter frequency response data is equal to the average of the rise and fall time constants as measured in the step function tests. For the curves of Fig. 16, the voltage gain was assumed to be unity; for this reason the magnitude approaches 0 db at low frequencies. The correlation between the theoretical and the experimental data is quite good and justifies the use of equation 11 to represent the 3-phase bridge circuit.

Conclusions

The emphasis in this paper has been on the presentation of experimental data which describes the transient response of the 3-phase bridge magnetic-amplifier circuit. From these data, a transfer function has been synthesized which represents the magnetic amplifier with reasonable accuracy. Since the transient response of the magnetic-amplifier circuit is quite complex, the experimental data have been presented in various forms. The reader may then select whichever form is most familiar to him and best meets his needs.

Discussion

G. E. Lynn (Westinghouse Electric Corporation, Baltimore, Md.): This paper is a welcome addition to the literature on a somewhat neglected portion of the magnetic-amplifier field. The approximate solutions to the dynamic response have been so widely accepted that most investigators have apparently assumed that further study is not worth while. Examination of the fine structure of dynamic-response curves of various circuits, however, reveals more than one apparent anomaly such as the "ramp function" response of the 3-phase amplifier.

In reference to the ramp function, I suggest that the author consider the following explanation in place of the accommodation process presented in his paper. For simplicity in explaining the mechanics of the ramp function response phenomenon, the circuit of Fig. 17 will be substituted for Fig. 1 of the paper. While the circuit of Fig. 17 is more complicated componentwise, its mechanics can be more easily demonstrated.

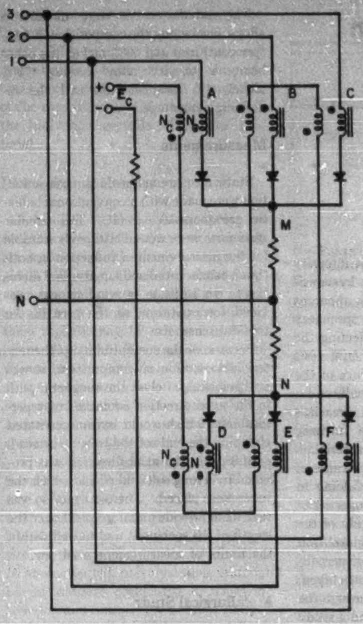
The author has stipulated that a large external resistance was inserted in the control circuit to remove the exponential portion of the transient. The amplifier may therefore be considered a fast-response type, each of the six cores behaving essentially as it would in a half-wave self-saturating circuit, since the cores are effectively decoupled from each other by the large control circuit resistance. As is well known, the dead-time or transportation lag of a half-wave circuit depends upon the instant of time in the cycle of supply frequency at which the step change of input voltage is applied.

The circuit under discussion consists of six cores and the phase relations are such that a reset period of one core begins every 60 electrical degrees, as shown in Fig. 18(B). The rectified phase to neutral voltages are shown for reference in Fig. 18(A). For the purpose of explanation, it will be assumed that a steady state control voltage exists before the step change in control voltage is applied and that this steady-state voltage produces a firing angle at the time of peak applied voltage in the gating interval of each core. The magnitude of the step will be assumed to be sufficiently large to produce a new steady-state firing angle retarded 30 degrees from the old. The step change in control voltage will be applied at time $t=t_0$ arbitrarily chosen as the time when core C has just completed its reset as shown in Fig. 18(B). It can be seen that core E has nearly finished its reset interval, core A is four-sevenths of the way through reset, core F has barely started, and cores B and D are in their gating intervals. It will be assumed that the amount of flux reset in a core is proportional to the length of time a step change of voltage is applied during a reset interval. Although this proportionality is not strictly achieved, the assumption will suffice for a qualitative description. Since the change in input occurs at the end of a reset interval for core C, the firing angle of this core in the next gating interval will not be affected. The firing angle of core E, however, will be retarded two-sevenths of the steady-state firing angle difference, that of core A four-sevenths, etc. The output voltage as viewed across points M and N of Fig. 17 will be as shown in Fig. 18(C). Steady-state is seen to be achieved at time $t=t_1$, 11/12 cycle after the application of the step change in input voltage. Dead time in this case is a little over 1/3 cycle. Had the step input been applied 1/12 cycle earlier or later, the dead time would have been 1/6 cycle and the transient would have been completed in 5/6 cycle. The latter figures are seen to be in good agreement with the author's measured values of 0.17 cycle dead time and 0.7 to 0.8 cycle for full response.

The existence of the ramp function response would thus be explained as being caused not by "an accommodation process in the cores whereby the cyclical core flux adjusts itself from operation on one minor hysteresis loop to another," but as existing simply because six cores must change their firing angles in the length of time reserved for two cores in a single-phase full-wave circuit or for one core in the half-wave circuit.

While it is true that a path for possible neutral currents exists in the circuit of Fig. 17, it would appear from the 3-phase symmetry of the circuit of Fig. 1 that the transient behavior of the two circuits would be essentially similar. For this reason it is felt that the foregoing explanation of the transient response is valid for both.

F. J. Ellert: The author appreciates Mr. Lynn's contribution in discussing in detail



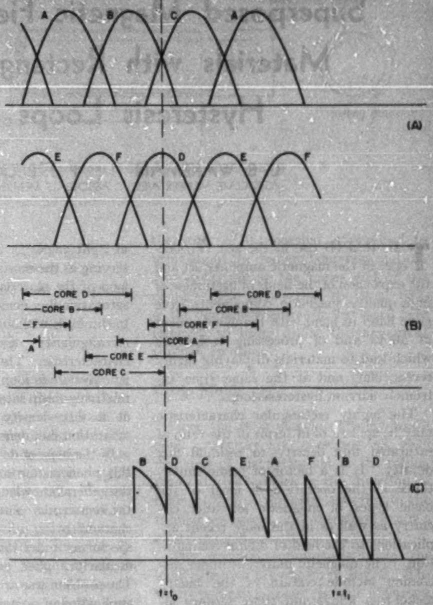


Fig. 17 (above left). Revised circuit for discussion

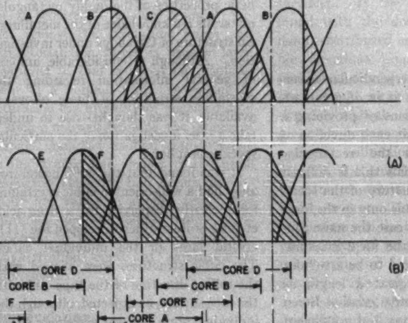
Figs. 18 (above right) and 19 (below left)

A—Reference voltage wave shapes
B—Resetting intervals
C—Output voltage transient



the cause of the ramp function. The details were also brought out during the author's oral presentation of his paper and it is gratifying to record agreement on this part of the discussion.

It will be seen from Fig. 18(B) that three cores (E, A, and F) will traverse minor hysteresis loops which are intermediate, namely between the steady-state loops before and after the transient. The term accommodation is used to indicate the existence of intermediate hysteresis loops.

The output voltage as viewed across points M and N, and shown in Fig. 18(C) is in error. (There are two different points in Fig. 18(C), both being designated by N. One N designates the transformer neutral, and the other designates the star point of three rectifiers. To clarify the following, the transformer neutral will be designated by N'.) The output voltage of the circuit shown in Fig. 17 is the sum of the voltages between MN' and $N'N$. Using exactly the same premises as Mr. Lynn, the correct output voltage (between M and N) is shown in heavy lines in Fig. 19(C). It will be readily recognized that Mr. Lynn's output voltage of Fig. 18(C) is deficient by the amounts shown in shading in Fig. 19(C).

Superposed Magnetic Fields in Materials with Rectangular Hysteresis Loops

C. B. WAKEMAN
ASSOCIATE MEMBER AIEE

F. J. BECK
ASSOCIATE MEMBER AIEE

THE RAPID rise in the last two decades of the magnetic amplifier art and the expansion of the fields of usefulness of high-quality magnetic components have gone hand in hand with the development of alloys and of processing techniques which lead to materials displaying highly rectangular, and at the same time extremely narrow, hysteresis loops.

The highly rectangular characteristic may be spoken of in terms of the ratio of saturated flux density to residual flux density. It is a factor of prime importance in the operation of most of the basic types of magnetic amplifier circuitry as well as in the more recent applications to the field of digital computation. The magnetic materials under discussion include certain of the binary nickel-iron alloys and those ternary alloys which include small percentages of molybdenum. These alloys are of interest not only because of their utility as practical circuit elements. Their peculiar crystalline properties provide the means of verifying and extending many of the theories of magnetic action which have been developed on the basis of experiments with single crystals.

In addition to their remarkable hysteresis properties, these materials exhibit interesting characteristics when subjected to simultaneously applied perpendicular fields. The relative simplicity of fabrication of the polycrystalline and grain-oriented specimens has permitted an experimental investigation of these characteristics to be carried out in conjunction with an analytical study.

The application of a uniform fixed field at right angles to the magnetic intensity serving as the excitation for the hysteresis loop of the material causes the apparent saturation flux density of these specimens to diminish without greatly affecting the rectangularity of the new hysteresis characteristic. The coercive force of the new hysteresis loop remains small, and a relatively sharp saturation level is reached at a flux density below the intrinsic saturation flux density of the material.

In the hope of determining the cause of this phenomenon and thereby adding to the general knowledge of the properties of the rectangular materials, a study of the characteristics of selected nickel-iron specimens under the influence of perpendicularly applied fields was undertaken. The problem was approached through the application of domain theory and a study of the crystalline properties of the magnetic materials.

Specimens

In any study of perpendicular superposed magnetic fields it is of great advantage to find a means of providing a closed magnetic path in each direction of measurement. With the rectangular hysteresis loop materials this is difficult because the physical nature of the specimens which are available only in the form of thin tapes. In this case the most convenient approach to the ideal measurement geometry appeared to be a tubular specimen having as great a length as possible, a small, effective cross-sectional area in the axial direction, but a sufficient number of circumferential tape wraps to provide good magnetic closure in the toroidal sense. Samples were obtained having the geometry outlined, with dimensions as shown in Fig. 1. In each specimen, ten wraps of tape having a thickness of approximately 51 microns were wrapped on a ceramic tube. The rolling direction corresponds to the circumferential direction around the tube. Each of the cores was placed on the tube prior to the final heat treatment appropriate to the material.

The tubular cores were nickel-iron alloys, one having the composition of 50% (per cent) iron and 50% nickel, the other being a ternary alloy having 79% nickel, 4% molybdenum, and the remaining percentage iron.

Measurements

Static measurements of magnetic induction were made with a conventional ballistic galvanometer circuit. The tubular specimens were wound with coils suitable for the measurement of induction in both the circumferential and longitudinal directions. In addition, a winding was provided for excitation of the core in the toroidal sense.

Because of the susceptibility of the materials to torsion or compression, it was not practical to close the magnetic path in the axial direction by means of a permeameter which would have necessitated clamping the ends of the tubes. Instead, excitation in the axial direction was provided by a long solenoid within which the tubes were placed. The construction was such as to provide a uniform field over the length of the specimen, and to well within the limits of measurement accuracy.

Metallurgical Study

Fundamental to a study of the magnetic properties of the highly rectangular materials is a knowledge of the metallurgical structure of the alloys under investigation. Although a considerable amount of general information regarding the crystalline structure of these alloys is available, it was thought wise to undertake a brief investigation of the particular specimens at hand.

It was found that the 50% nickel-iron alloy had a well-oriented cubic crystalline form clearly displayed by a deep-acid-etching process which developed the (111) crystal faces of the individual cubes. The cubic structures were aligned with the rolling direction of the tape and with the tape surface, as expected, although the individual grain size was extremely small. X-ray transmission patterns were also taken. These confirmed the findings that the structure consists of extremely small grains, each of which is well oriented to the co-ordinates of the tape. The easy directions of magnetization for an alloy of this composition are along the cube edges, and thus the easy directions of magnetization for the tape as a whole are parallel to the rolling direction, and across the rolling direction.

X-ray transmission patterns of the crystal structure of the *4-79* molybdenum

This paper is part of a dissertation presented by C. B. Wakeman for the degree of Doctor of Philosophy at Yale University.

permalloy showed the Debye rings to be typical of a completely unoriented specimen. This predicts a nondirectional magnetization characteristic for this material because of the random orientation of the easy directions of magnetization of the individual crystals within the material.

Discussion of Results

According to the domain theory of magnetization, all ferromagnetic materials are made up of completely saturated regions. Within a given region the magnetic moment vectors of all of the atoms are aligned with one another; yet each of these regions may be oriented in a different direction. The magnetization of the material as a whole is the vector sum of the magnetizations of the individual regions or domains. The average magnetization, when no external field is applied, may well be zero.

The magnetization process in the material may be one of rotation of the intensity of magnetization vectors of the domains, or it may be a process of domain boundary motion changing the relative size of the variously oriented domains. In an unoriented, polycrystalline material having nonzero coefficients of magnetostriction and anisotropy, a major portion of the energy required to saturate the material goes into domain rotation. The energy required to produce domain rotation against the crystalline forces and magnetostriction forces is usually large compared to that required for displacement of a domain wall. In raising to saturation the intensity of magnetization of such a magnetic sample, the process of domain boundary motion corresponding to the straight-line portion of the usual magnetization curve first occurs at relatively low values of applied field. The rotational process follows later, corresponding to the curved portion of the magnetization curve as saturation is approached.

Nomenclature

H = total magnetizing force
H_T = total effective transverse magnetizing force (in the rolling plane, normal to the rolling direction)
H_{Ta} = applied transverse magnetizing force
H_{Ro} = magnetizing force parallel to the rolling direction
B_T = flux density in the rolling plane, normal to the rolling direction
I_{Ro} = intensity of magnetization, parallel to the rolling direction
I_T = transverse intensity of magnetization, in the rolling plane, normal to the rolling direction
I = intrinsic intensity of magnetization
N = demagnetizing factor
E = total crystal energy
E_A = energy of crystal anisotropy

Electromagnetic units are used throughout the paper.

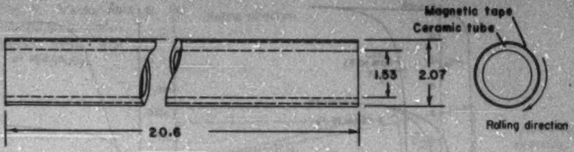

Fig. 1. Dimensions of tubular cores (centimeters)

50% Nickel-Iron Alloy

Consider now a magnetic material from which the randomness of the crystalline structure has been removed, and each of the cubic elements of the lattice is fairly closely aligned with its neighbor. This situation has been shown to exist in the 50% nickel-iron specimen under investigation. If the cubic lattice is arranged, as has been indicated, with the cube edge lying parallel to the rolling direction, it should be possible to shift the entire saturation flux solely through the process of domain boundary motion, as in the case of a properly oriented, single crystal specimen. If the material is initially found with the domain directions randomly distributed in each of the six possible directions, applying a small field parallel to any of the crystal-axis directions should serve to align each of the domains with the field. Since the field direction corresponds to an easy magnetization direction for each of the crystals, the anisotropy energy required to obtain complete field alignment would ideally be zero. The magnetization curve in this case will rise to the saturation value of intensity of magnetization with very small values of fields, and will saturate sharply. The value of applied field required to bring about the domain boundary motion is dependent on a number of factors, which include impurities and local strain effects.

In the 50% nickel-iron tapes the crystal orientation is not perfect, and strain removal has not been complete. The major portion of the magnetization takes place, however, with very small fields applied, and the saturation is quite abrupt. These features are illustrated by the static hysteresis loop for the tubular specimen of this material, as shown in Fig. 2. The straight sides of the loop show that a uniform magnetizing force of the order of 0.1 oersted is required to bring about the domain boundary motion. The curvature at the upper end of the characteristic shows that the final 10% of the domains requires an increased field strength to bring about the alignment through rotation.

Cross Fields

Since the 50% nickel-iron alloy has a cubic structure, it possesses an easy direction of magnetization in the rolling plane at right angles to the direction of rolling. This is the axial direction in the tubular specimens and, therefore, is not a closed magnetic path.

The magnetic characteristics in the axial direction are shown in Fig. 3. The sharp saturation point is still apparent, but, in order to obtain from these data the true hysteresis loop of the material in the axial direction, it would be necessary to know the demagnetizing factor for the particular tube geometry. Furthermore, if good results are to be obtained, the demagnetizing factor must be known fairly accurately. The effective field strength acting axially on the tube is the difference between the external applied field strength of the solenoid and the field due to the surface density of magnetic charge induced at the ends of the specimen. Expressed quantitatively

$$H_T = H_{Ta} - NI_T \tag{1}$$

The transverse intensity of magnetization, however, is a function of $\mathbf{H}_T$ and $\mathbf{B}_T$.

$$B_T = H_T + 4\pi I_T \tag{2}$$

So

$$H_T = H_{Ta} - \frac{N}{4\pi}(B_T - H_T) \tag{3}$$

A calculation of demagnetizing factor may be made by using the curves of Fig. 3. If the magnetizing force required for small values of transverse induction is considered negligible, it is possible to find the factor which will cause the magnetization curve for the 50% nickel-iron tube to lie vertically along the B_T axis, for value of

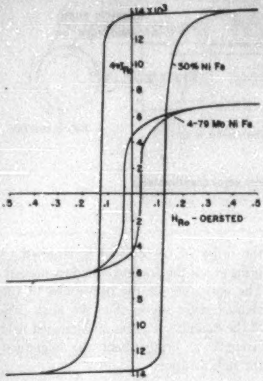

Fig. 2. Static characteristics of tubular cores in the circumferential direction

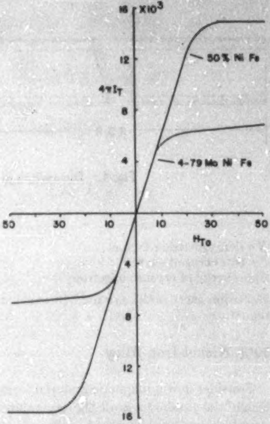

Fig. 3. Axial magnetization characteristics of the tubular cores

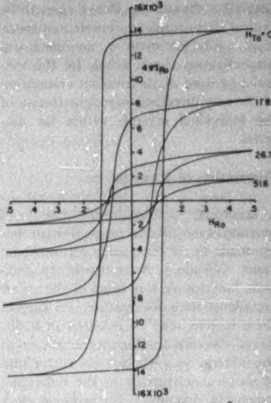

Fig. 4. Hysteresis loops of 50% nickel-iron alloy tube with various applied transverse fields

flux density less than about 8.0 kilogauss. Making use of equation 1, N is found by trial to be

$$N = 0.02 \tag{4}$$

The demagnetizing field is caused by the surface distribution of magnetic charge induced at the ends of the specimen, and the demagnetizing factor is properly so-called only when the induced charge arises from a uniform intensity of magnetization within the sample. This happens with a spheroidal configuration, since the magnetization is then uniform throughout the material, but not in a rod or a tubular sample. It should be recognized that any discussion of a demagnetizing factor as a constant is not accurate for a rod on tubular specimen. Examining the properties of the material under the influence of superposed fields, however, should provide further information on this point, as well as on the manner in which the magnetic changes take place.

Superposed Fields

Consider that situation which exists when two fields are superposed at right angles in the 50% nickel-iron tubular specimen. As has been shown, each field is oriented to lie along a direction of easy magnetization. By first applying a fixed field, H_{Ta}, along the axis of the tubular specimen, a sufficient number of domains will be aligned with the field in the axial direction to cause a demagnetizing field which is very nearly equal, and opposite, to H_{Ta}. Since the hysteresis loop width for all flux levels below saturation is a small and essentially constant quantity, and since the demagnetizing factor is relatively large, the number of domains aligned in the axial direction will be very nearly proportional to the applied field. We can write from equation 1 when $H_T \ll H_{Ta}$

$$H_{Ta} = NI_T \tag{1A}$$

If the transverse induction were slightly reduced by the action of the superposed field H_{Ro}, the effective transverse field would rise sharply, tending to return these domains to the transverse direction. The remaining domains, however, would be free to be acted upon by the field in the rolling direction, and for small values of H_{Ro} would be essentially independent of H_T. The effect is much as though a part of the magnetic material had been physically removed, with the result that the total saturation flux is lowered, but the requirements of the magnetizing field in the rolling direction are left unchanged.

The characteristics of the tubular sample illustrate this action. In Fig. 4 hysteresis loops of B_R versus H_{Ro} are plotted for selected values of applied transverse field. As the transverse field is increased, the apparent saturation flux density in the rolling direction decreases. The rectangularity of the loop is fairly well maintained, however, until the transverse field becomes so large that saturation is reached, and $I_T \cong I$. Beyond this point, there should be no free domains which are not under the direct influence of the transverse field.

Case I. $H_{Ta} > NI$

In this case a large transverse field is applied along the tube axis, so that all of the domains are caused to align with the cross-rolling direction of the tape. In order for this to be true, according to equation 1, H_{Ta} must be larger than NI, and the effective transverse field is given by

$$H_T = H_{Ta} - NI \tag{1B}$$

If a field H_{Ro} is then applied in the rolling direction there will be a net field acting on each of the crystals which is not parallel to one of the crystal axes. Referring to Fig. 5, the total magnetizing field H is the vector sum of H_{Ro} and H_T, and lies at an angle θ_3 which depends upon the relative magnitude of these components. It should be possible to calculate, using energy relations, the angle of domain rotation θ_2 resulting from the application of these fields. The rotation angle must represent a condition of minimum crystal energy, which, if the energy of magnetostriction may be considered negligible, is given by the sum of the field energy and the anisotropy energy. The anisotropy energy may be expressed in terms of the cosines of the angles between the field and the cubic crystalline directions

$$E_A = K_0 + K_1(\alpha_x^2\alpha_y^2 + \alpha_y^2\alpha_z^2 + \alpha_z^2\alpha_x^2) + K_2\alpha_x^2\alpha_y^2\alpha_z^2 + \ldots \tag{5}$$

When this result is simplified for the particular geometry, and the energy of the field is added, the expression for the total energy becomes

$$E = K_0 + K_1 \sin^2\theta_2 \cos^2\theta_2 - HI\cos(\theta_2 - \theta_3) \quad (6)$$

If the angles are related by the use of equation 1 and Fig. 5

$$H_{Ro}\cot\theta_3 = H_{To} - NI\cos\theta_2$$

and

$$H = \frac{H_{Ro}}{\sin\theta_3}$$

With these substitutions equation 6 reduces to

$$E = K_0 + K_1 \sin^2\theta_2 \cos^2\theta_2 - H_{Ro}I \times \left[\cos\theta_2\left(\frac{H_{To} - NI\cos\theta_2}{H_{Ro}}\right) + \sin\theta_2\right] \quad (6A)$$

If this energy expression is differentiated with respect to θ_2 and the resulting expression is set equal to zero

$$\frac{K_1}{2}\sin 4\theta_2 + H_{To}I\sin\theta_2 - H_{Ro}I\cos\theta_2 - NI^2\sin 2\theta_2 = 0 \quad (6B)$$

Solving this equation will show the presence of a single maximum and minimum energy condition for the intensity of magnetization vector in the range $0<\theta_2<\pi/2$. The solution representing the minimum energy point can be chosen by inspection of the vector diagram of Fig. 5. For the situation in which $H_{Ro}<H_T$, the value of θ_2 representing the minimum of crystal energy must lie in the range

$$0<\theta_2<\tan^{-1}\frac{H_{Ro}}{H_T} \quad (7)$$

In order to make use of equation 6(B) for numerical computation, it is necessary to assign values to the constants N, I, and K. The demagnetizing factor N will be assumed to be equal to the measured value of Equation 4 as a first approximation.

K_1 is the first anisotropy constant and is a positive number for nickel-iron alloys of less than about 73% nickel content. Bozorth and Walker[1] have shown values ranging in the neighborhood of 7×10^3 ergs/cm^3 (per cubic centimeter) for the 50% alloy, while an earlier summary by McKeehan[2] gives the value as 3.3×10^4. This wide range is indicative of the variations to be expected with different methods of handling. The later results of Bozorth and Walker are probably more nearly representative of the tape samples, and the value $K_1=10^4$ ergs/cm^3 will be used for computation.

It is possible with these values to calculate the expected rotation angles for any given applied longitudinal and circumferential fields. The components of the intensity of magnetization in the two directions may then be obtained and compared with the values measured with the tubular specimens. This comparison was made, and it was found that, while the slopes of the calculated curves agreed quite well, the calculated value always fell below the measured points. For each of the measured curves, it appears that the material is not entirely saturated in the transverse direction in spite of the large value of applied field. A small group of domains appears to remain independent of the transverse field and is easily influenced by circumferential fields of the order of the coercive force of the material.

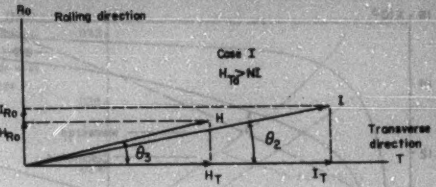

Fig. 5. Vector relationships for superposed fields with H_{To} large

The reason for the independent action of this small group is not clear. It appears that in this group there are additional factors in the energy relations which have not been accounted for. One factor might be a magnetostrictive effect caused by local stresses within the material; but, as will be shown, this explanation is not adequate for all the materials under investigation since they have widely different magnetostrictive constant although the measured effect is much the same in all cases.

If this deviation from the calculated values of I_{Ro} is accounted for by assuming that such a group of independent domains exists, the remainder of the magnetization process appears to take place, much as has been proposed, by a process first of alignment of the major proportion of the domains with the transverse axis and then a rotational process out of the transverse axis as H_{Ro} is increased from zero. The magnitude of the independent domain group may be estimated by extrapolating the curves for the various values of H_{To} back to the axis of ordinates.

If the values of I_{Ro} are recomputed by removing the group of independent domains from the calculations and adding it arithmetically to the value obtained from equation 6(A), the curves fall as shown in the lower portions ($26.7<H_{To}\leqslant101$) of Fig. 6.

As the value of the transverse field is decreased, a point will be reached at which the effective transverse field and the circumferential field will be equal. At this point $\theta_2=\pi/4$. In terms of the properties of a single cubic crystal, any further decrease in the axial field should lead to a minimum energy condition with all of the domains oriented more closely with the circumferential direction than with the axial direction.

If the domains attempt to shift to this lower energy condition, however, the demagnetizing field in the transverse direction will decrease, causing a corresponding increase in the effective transverse magnetizing force. The increased H_T will in turn reduce the angle made by the total magnetizing vector with the T axis. This reduction in θ_2 must reach an equilibrium point at $\theta_2=\pi/4$. Below this value, H_T is larger than is consistent with the value of demagnetizing field. For θ_2 larger than this value, all domains must lie near the rolling direction axis, making H_T too large. If $\theta_2=\pi/4$, however, the transverse direction and the rolling direction represent conditions of equal crystal energy. Thus the domains can divide, with a part of the total lying nearly parallel to each of the axes.

Under these conditions, the magnetization changes taking place cannot be divided sequentially, with the domain boundary motion occurring first, and the rotation taking place later as the applied field is increased. Here the domains will shift alignment between the rolling direction and the transverse direction by a process of 90-degree boundary wall displacement, and, at the same time, both groups of domains will be rotated out of exact alignment with the respective axes by the action of the total effective field.

To calculate the conditions of minimum energy in the crystal, it is necessary, therefore, to account for the field energy and the anisotropy energy of each of these groups of domains.

Case II. $H_T=H_{Ro}$

If H_{Ro} is increased beyond the value corresponding to the coercive force of the material, domains will be removed from the transverse axis to align with H_{Ro}. However, the demagnetizing field will grow until an equilibrium is reached at $H_T=H_{Ro}$. The conditions will then be represented by the vector diagram of Fig.

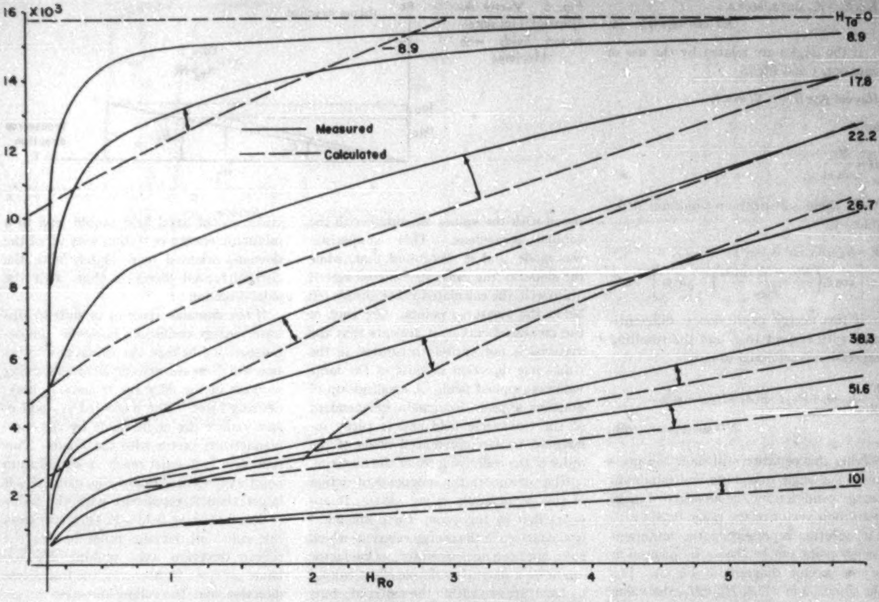

Fig. 6. Comparison of calculated and computed magnetization curves for the 50% nickel-iron alloy tube

7. The two groups of domains are represented by I_1 and I_2 respectively, and make angles of θ_1 and θ_2 with the rolling and transverse directions.

The energy expressions may be written for each of these groups of domains if an assumption is made regarding the value of the anisotropy constant for a group of domains which represent less than the saturated value of magnetization. For lack of better information, it has been assumed that the anisotropy constant varies with the intensity of magnetization. Thus, representing the constants of the two groups by K_{1A} and K_{1B} respectively gives

$$K_{1A}=\frac{K_1I_1}{I},\quad K_{1B}=\frac{K_1I_2}{I} \qquad (8)$$

The total crystal energy will be the sum of the respective field and anisotropy energies of the two domain groups. This reduces to the form

$$\begin{aligned}E=K_0+\frac{K_1I_1}{8I}(1-\cos 4\theta_1)-\\ H_{Ro}I_1(\cos\theta_1+\sin\theta_1)+\\ \frac{K_1I_2}{8I}(1-\cos 4\theta_2)-\\ H_{Ro}I_2(\cos\theta_2+\sin\theta_2) \qquad (9)\end{aligned}$$

If this equation is differentiated with respect to the variables θ_1, θ_2, and I_1, and if the assumption is made that the total saturation intensity of magnetization is represented by the sum of the components I_1 and I_2, we are left with the relation

$$\frac{K_1}{2}\sin 4\theta_1-H_{Ro}I(\cos\theta_1-\sin\theta_1)=0 \qquad (10)$$

and

$$\theta_1=\theta_2$$

The distribution of the domains can be calculated from equation 1, if it is written in the form

$$\begin{aligned}H_{Ro}=H_{Ta}-\\ N[I_1(\sin\theta_1-\cos\theta_1)+I\cos\theta_1] \qquad (1C)\end{aligned}$$

This provides the means of calculating the expected intensity of magnetization in the circumferential and longitudinal directions for various values of the applied magnetizing fields. If this computation is carried out, the calculated curves are again found to lie below the measured values in all cases.

For each of these calculated values, the constants I, N, and K, mentioned in the foregoing have been used. I, being a directly measured quantity, should be open to little question. The improper choice of the anisotropy constant will basically have an effect upon the slope of the curve rather than on the absolute value. The demagnetizing factor, however, plays an important part in setting the level of the calculated curves. It is usually thought of as a constant dependent only upon the geometry of the magnetic sample. This is strictly true only for a spheroidal specimen. In the case of a rod or a tube, the surface charge distribution will be to some extent dependent upon the intensity of magnetization, so that the demagnetizing factor will change slightly as the magnetization varies. To determine how N varies for the particular tube geometry used, a series of magnetization characteristics were taken in the axial or transverse direction for various values of H_{Ro} applied circumferentially. The curves show a definite trend toward a slope which decreases as H_{Ro} is increased. By computation from each of these curves, an effective value of demagnetizing factor shows that N varies with the circumferential field, approximately as shown in Fig. 8.

A more correct calculation of the magnetization characteristics should be ob-

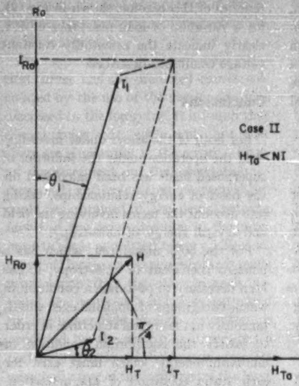

Fig. 7 (left). Vector relationships for superposed fields with H_{Ro} large

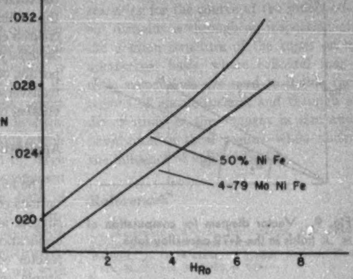
Fig. 8 (right). Variation of effective demagnetizing factor with circumferential field



tained, therefore, if the value of N is not held constant in the solution of equation 1(C), but is permitted to vary with H_{Ro} according to the curve of Fig. 8. Such a calculation has been carried out for the values of transverse field which correspond to the measured curves in the upper portion ($0 \leq H_{To} \leq 26.7$) of Fig. 6. The calculated curves are plotted in Fig. 6 for direct comparison.

A similar computation for the lower curves of Fig. 6 indicates that the effect of the variation of N is not appreciable here because of the large transverse applied field.

Some of the discrepancies between the measured and calculated curves may still be accounted for by an incorrect evaluation of the demagnetizing factor, but certainly not all may be. The points of least agreement are at low values of H_{Ro}, which is the region in which the approximation of ideal crystalline characteristics are poor. As is shown by the curvature of the magnetization characteristics for the tube with zero transverse field applied, a certain proportion of the magnetization changes are rotational, and the crystal orientation cannot be taken as perfect.

The greatest question at present, however, is the source of the seemingly independent domains which are easily influenced by the circumferential field even in the presence of extremely high axial fields.

4-79 Molybdenum Permalloy

The permalloy tube exhibits a considerably less rectangular hysteresis characteristic than the 50% nickel-iron alloy. This is undoubtedly due to the lack of orientation of the crystalline structure and the consequent need to rotate the magnetic domains against the forces of crystal anisotropy. Though not zero, the anisotropy constant of the permalloy is quite small. Bozorth and Walker[1] place the composition requiring zero anisotropy energy at about 76% nickel for the binary nickel-iron alloys which have an unoriented structure. On this basis, the 79% nickel alloy should have a small negative value, probably not exceeding -2×10^3 ergs/cm^3. The results obtained with the addition of molybdenum do not appear to differ with these findings. The magnetic characteristics of the permalloy tube are shown in Fig. 2.

Cross Fields

The general process of magnetization has been described in terms of two phenomena: the growth of domains by the motion of the boundary wall separating regions of different magnetic orientation within the crystal, and the rotation of whole domains away from the easy crystalline directions of magnetization toward a direction parallel to the applied field. In respect to the permalloy tapes, the field required to bring about boundary wall motion, roughly equal to the coercive force of the material, is extremely small. Further, because of the little energy of anisotropy required by the crystal, the magnetization vector can easily be rotated away from the preferred direction of magnetization, which in this case is parallel to the (111) axis of the individual crystals and is randomly oriented with respect to the tape dimensions. Therefore, the total magnetization vector should be aligned with the direction of the total applied field for values of field strength greater than one or two oersteds. If the assumption is made that this must be done, the characteristics of the tubular core may be calculated.

Referring to Fig. 9, if magnetizing fields are applied simultaneously in the rolling direction and the transverse direction, a resultant total magnetizing force H will lie at an angle θ_3 with respect to the transverse axis. This field is the sum of the H_{Ro} and H_T vectors. Thus

$$\tan \theta_3 = \frac{H_{Ro}}{H_T} \tag{11}$$

The effective field in the transverse direction, H_T, is dependent upon the transverse intensity of magnetization and the demagnetizing factor. Thus the H_T may be expressed as before in terms of the applied field and the component of intensity of magnetization in the transverse direction.

$$\tan \theta_3 = \frac{H_{Ro}}{H_{To} - NI \cos \theta_2} \tag{12}$$

where θ_2 is the angle between the total magnetization vector and the T axis.

In accordance with the assumption that the magnetic intensity vector and the intensity of magnetization vector are co-directed, equation 12 becomes

$$H_{To} \tan \theta_3 - NI \sin \theta_3 - H_{Ro} = 0 \tag{13}$$

This equation can be solved graphically for θ_3, permitting I_{Ro} to be computed for various values of H_{Ro} and H_{To} corresponding to the measured curves of Fig. 10.

The curves obtained from this computation have been plotted in Fig. 10. For each of these calculated points, the demagnetizing factor has been adjusted according to the data presented in Fig. 8. It will be noted that the agreement between the measured and calculated curves is quite good for small values of transverse field; but that as the values of H_{To} are made larger, an increasing discrepancy appears. This discrepancy is particularly large at low values of the circumferential field.

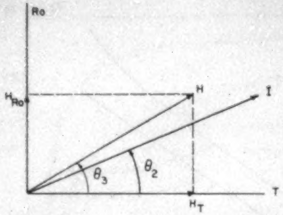


Fig. 9. Vector diagram for computation of fields in the 4-79 permalloy tube

At very small values of H_{Ta}, the calculated curves show a sharper rectangularity than do the measured values. This is undoubtedly accounted for by the error introduced with the assumption of a negligible anisotropy energy term. Since some anisotropy energy is required to achieve complete alignment of the magnetization and field vectors, it is not surprising to find the measured curves exhibiting a curvature rather than a sharp break when approaching saturation.

At high values of transverse applied field, the measured rolling direction magnetization is everywhere greater than the corresponding calculated points. The measured curves show a sharp rise in the circumferential intensity of magnetization at small values of applied field, indicating that the material is not acting exactly as has been assumed. In a manner similar to the 50% nickel-iron tape, the permalloy measurements show that a group of domains in the rolling direction are affected by a small circumferential field, even in the presence of a large transverse magnetizing force. It is concluded that the magnetization process cannot be completely described in terms of a rotation of the total I vector. For low values of H_{Ro}, the rolling direction flux density is increased either by domain growth through boundary wall motion, or by rotation of a portion of the magnetic domains out of the transverse direction through a substantial number of degrees.

Applications

The hysteresis loops shown in Fig. 4 for various conditions of cross magnetization suggest an interesting possibility for the application of transverse fields in magnetic reactor control problems. The standard simple series, or parallel power reactor circuits provide a control of alternating current in a load circuit which is nearly proportional to a d-c control current flowing in a control winding on the reactor.[3] This is less than satisfactory if the load being controlled has a varying impedance, since the output characteristic of such a reactor is essentially high impedance and provides a constant current drive. If, however, a single core reactor were provided with a means for the application of a variable transverse field, it should be possible effectively to control the saturation flux density of the reactor, and thus control the volt-time integral which the core would accept before firing. This in turn would make the firing angle, rather than the output current, a direct function of the control field, and make the output impedance characteristics relatively low. This is to say that the average voltage measured across a varying load impedance placed in series with such a reactor would remain constant.

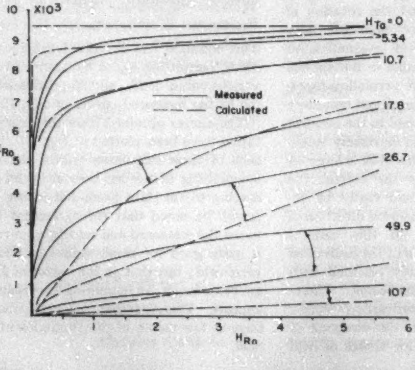
Such a reactor was built with a standard toroidal core of oriented 50% nickel-iron tape. A transverse control field was applied by placing the core between the poles of an electromagnet. The control characteristics of this reactor, shown in Fig. 11, for a variation of load resistance of 5:1, clearly indicate the essentially constant voltage conditions described.

Conclusions

For both of the alloys under investigation, the operation under the influence of superposed fields has been calculated on the basis of energy relationships, taking into account the terms involving the field and crystal energy of anisotropy.

For the 50% nickel-iron, which has a nonzero coefficient of anisotropy, it has been necessary to postulate a condition in which two groups of domains exist simultaneously in the crystal structure, in order to satisfy the equilibrium condition of minimum energy which must exist for each static condition of magnetization. These two domain groups differ in size and orientation in accordance with the relative magnitudes of the two superposed fields. This is unlike the situation which exists when a high-permeability material is magnetized by a single field, because as two domain groups change both size and orientation, the processes of domain rotation and boundary wall displacement occur simultaneously within the crystal. Under the influence of a single field, the orientation of the magnetic domains normally occurs first through domain growth in the crystal direction which is most nearly oriented with the field, and further increases in magnetization occur exclusively through domain rotation.

It was possible to make the assumption that the anisotropy constant was negligible for the 4-79 permalloy tape specimen, and that the field and magnetization vectors are at all times codirected. In this case, the two domain groups mentioned merge into a single



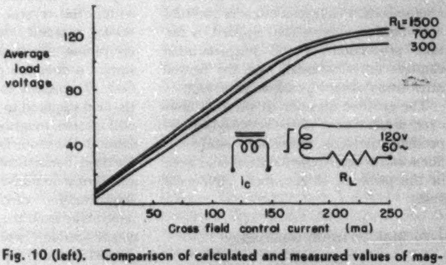


Fig. 10 (left). Comparison of calculated and measured values of magnetization in the 4-79 permalloy tube

Fig. 11 (above). Control characteristics of the cross-field reactor

group, and the field energy term alone determines the equilibrium of magnetization in the material.

In comparing the measured magnetization curves and the predicted curves calculated by the use of the energy relations discussed in the foregoing, it is found that discrepancies exist each time, but that there are similarities in the errors. First, an improvement in the correlation of measured and calculated characteristics could be obtained if the demagnetizing factor of the axial direction in the magnetic tubes is permitted to vary. Second, if one of the two superposed fields is made much larger than the other in each material, the material is not truly saturated by the larger field though saturation is predicted by the energy relations, but a certain proportion of the domains remains essentially free of the influence of the large field and is easily acted upon by the perpendicularly applied field.

In addition to eliminating the question of a demagnetizing factor from the general interpretation of the results, finding a means for closing the magnetic paths in both directions of measurement might permit a close inspection to be made of the source of the independent domains which do not appear to be influenced by large applied fields. Since this phenomenon has been found to be present in both of the alloys under discussion, it is apparently not primarily associated with the crystal anisotropy or magnetostriction properties of the materials, nor with the presence or lack of crystalline orientation. These factors vary greatly among the alloys studied, and yet the phenomenon is exhibited approximately equally by both. It is possible that the most profitable direction of study in searching for the source of the independent domains is through an inspection of the domain structure of the tapes on a microscopic basis, where colloidal magnetic suspensions are used to define the regions of magnetization, and through a direct study of the changes in size and orientation of these regions when under the influence of applied fields.

Numerical Integration of Differential Equations on the 704 EDPM

H. H. ANDERSON
NONMEMBER AIEE

J. R. JOHNSON
NONMEMBER AIEE

Synopsis: To provide a convenient means for solving complex and nonlinear ordinary differential equations, a system has been devised which causes a *704* EDPM to behave like an analogue differential analyzer. Use of this system involves the interconnection of appropriate subroutines in a manner analogous to the interconnection of operational amplifiers in an analogue machine. The subroutines are designed so that the user may compile the required connections automatically, without much knowledge of digital computer coding. Solving differential equations by this method takes no more setup time than that required by analogue machines and in many cases may be a good deal faster. Integration is done by using Milne's formulas. The system automatically adjusts the integration interval to take advantage of portions of the solution which can be computed with large intervals at no sacrifice of accuracy. Nonlinear functions may be expressed by a table of values in storage.

A RELATED group of subroutines, called NIDA (Numerically Integrating Differential Analyzer) has been prepared for the *704* EDPM which facilitates the numerical solution of ordinary differential equations. By using the NIDA system, a person without much experience with *704* coding can quickly and conveniently solve a set of simultaneous ordinary differential equations. The system is applicable to equations of any order and degree, either linear or nonlinear.

The availability of these subroutines in conjunction with a *704* materially increases the value of the *704* to an engineering development organization. Long periods devoted to planning, coding, and debugging are eliminated and therefore the small problems which arise frequently can be economically solved by this method, often in a matter of hours. The NIDA system, on a *704*, can in most cases completely obviate the need for an analogue differential analyzer or similar devices. Differential equations which in the past have been solved only crudely, or perhaps not at all, by analogue methods, can now be numerically integrated at no sacrifice of time.

The operations which are performed by the *704* in executing the NIDA routines are essentially those used in desk calculator computations or other digital computer routines written to solve specific differential equations. By proper selection of conventions and linkages it is possible to place the necessary elements of differential equation integration routines in a few general-purpose subroutines. These subroutines can then be used as building blocks to form the complete program for any set of equations. The factor which was held most important in the design of NIDA was convenience of use. The parts were written so that compiling for a problem could be done easily and accurately by one not skilled in the art of *704* coding. Secondary in importance is the speed at which integration progresses in a solution. Fortunately, the *704* has enough inherent speed and flexibility so that very little speed was sacrificed.

Integration

Integration is accomplished by use of Milne's prediction and correction formulas. The information required by the integration subroutine consists of two tables of values, one table for present and past values of the integrand and one table for past values of the integral. Each table is composed of seven entries, each entry having been obtained from previous computation. As the solution progresses, the entries in the tables are shifted, dropping the oldest, and making room for the next value to be computed.

Paper 56-697, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 30, 1956; made available for printing May 29, 1956.

(b)
Interval Doubling of Table

Fig. 1. Variable table handling

A table, as described is required for every variable (each derivative is considered to be a separate variable) involved in the equation. The process of integration thus consists of entering a subroutine, specifying the location in storage of the two tables to be used by a subroutine.

For a given increment of the independent variable, that is, the variable of integration, each derivative is operated on twice. First, a formula makes use of previous values of the function and predicts a value of the integral for the present This predicted value is stored in a temporary location at the end of the table. Subsequently, a correction formula is applied to the table, including the predicted value, and a corrected value is obtained. This value is stored at the head of the table, representing the most recent value of the integral.

After having computed the corrected value, a comparison is made between the results of the two computations and if the two values do not agree within a specified amount, a process is initiated which effectively reduces the size of the integration interval being used. If the results of the prediction and correction computations agree too closely, a process is initiated which causes the integration interval to be doubled. This automatic adjustment of the interval size goes on without special arrangements on the part of user of the system, and affords a method of obtaining both small interval size when needed for accuracy as well as a large interval size for speed, when the accuracy requirements are satisfied.

A discussion of the mathematics of the integration subroutine is presented in the Appendix.

Algebra

The algebraic operations required in the solution of a differential equation, combined with integrations, completely specify the equations. Such operations as multiplication of derivatives by constants or other variables, summing of terms, and any other necessary arithmetic operations are coded directly in *704* machine language by the user of the NIDA system. This coding is straightforward, for the most part, and because of the built-in floating point arithmetic feature of the *704*, the coder need not concern himself with considerations of radix point or overflow. The use of *704* instructions for the algebraic portion of the equation is, in no way, a disadvantage of the system. On the contrary, it is this feature which most clearly establishes the superiority of NIDA over analogue methods. Multiplication, function generation, and other nonlinear operations (traditionally the weak points of analogue methods) are the most precise and easily performed functions in using NIDA. The user also has at his disposal all of the powerful logical operations available in the *704* instruction repertoire. The logical operations are particularly valuable when equations change form as the variables reach limits. An example of this might be the case of a 2-loop electric circuit, wherein the loops are coupled by an ideal diode. A logical testing instruction could be employed to sense when the diode current attempts to reverse and at this point switch the program to a different equivalent circuit.

Up-Dating

The essential core of the NIDA system, that which accounts for its ease of use and flexibility of application, resides in a subroutine called "up-dating." This is the part of the system which links all of the other parts together logically and exerts supervision and control. The update routines sees to it that the entries in the variable tables are shifted at the proper time. Up-date also keeps a running record of the value of the independent variable and the integration interval being used at any time.

As each correction integration is performed by the integration subroutine, a note is left with the up-date routine regarding whether the interval size should be increased, maintained, or decreased. The up-date routine, when executed, examines these notes regarding the accuracy of integration of each variable in the equation and if any one indicates that the interval should be decreased, then it is decreased. If all the notes indicate that the interval should be doubled, then it is doubled. In other cases the interval size is not disturbed.

When the solution of the differential equations begins each variable table contains only the initial value of the function, stored in the first cell of the table. Since Milne's formulas require four values of the variable, a special set of starting formulas is used to get started. Because it is convenient to have only one integration subroutine to link, the up-date subroutine works in conjunction with the integration subroutine, directing it to use the proper starting formula during the starting phase and also instructing it when to use a prediction or correction formula later on. If the situation arises which requires that the integration interval be reduced (error too large), the up-date routine causes the integration procedure to restart. That is, using the most recent computed value of each function as a new initial condition, the integration routine again employs the starting formulas with a very small starting interval. All values of each variable except the most recent are ignored.

If conditions arise which make it possible to increase the integration interval, this is done by doubling the interval and then discarding alternate entries in each variable table. This reduces the

Vol. 7
Pt. 1
1956

number of entries in each table from seven to four, and so the next time at which doubling can be performed is restricted to a time when seven entries have again accrued. The process of handling the variable tables is illustrated in Fig. 1.

Printing and Table Look-Up

Included in the NIDA system are two "convenience" subroutines, printing and table look-up.

The printing subroutine is capable of translating from floating binary and printing floating point decimal numbers, six to a line. The mode of entry to the print subroutine is flexible enough so that any number of quantities may be printed per entry.

Frequently, the integration interval is less than the interval for which results are to be printed. However, the printing of results is limited to those points which are desired. This control of printing is exerted by the up-date subroutine.

In order to handle easily any complicated functions which appear in the equations being solved, a table look-up subroutine can be used with a stored table of functional values and can supply the main routine with values when required. The table look-up subroutine uses a polynomial of high order for interpolation so a relatively small number of tabular values needs to be stored to achieve accuracy comparable to integration.

Stability of the Integration Formulas

Original plans for the logical organization of NIDA called for a halving of the integration interval when the predicted and corrected values for any integration did not agree within the specified allowable error. This method of reducing the interval size proved to be unsatisfactory because of the instability of Milne's integration formulas.[1] To avoid stability difficulties it was decided to restart the process completely, with the latest computed values as initial conditions, when reduction of interval size is called for. It was found by experiment that repeated restarts did not significantly affect the over-all accuracy of the solution.

Restarting has the disadvantage that it consumes a relatively large amount of time, as compared to interval halving. If Milne's integration formulas are replaced by stable formulas, it may be possible to use the interval halving procedure with a consequent decrease of solution time in most problems.

Fig. 2. Solution of the example differential equation

An Example of How to Solve an Equation Using NIDA

The foregoing has been an attempt to explain in general terms what the NIDA system is and how it works. In what follows, it will be shown in detail how the system is applied to the solution of an example differential equation (see Fig. 2). Consider

$$+\sqrt{\frac{d^2x}{dt^2}}-x\frac{dx}{dt}+x=A \tag{1}$$

The first step in preparing this equation for NIDA solution is to rearrange it, solving for the highest order derivative. This is commonly done in preparing equations for solution on most differential analyzers, and results in

$$\frac{d^2x}{dt^2}=\left(x\frac{dx}{dt}-x+A\right)^2 \tag{2}$$

An examination of this equation shows that three variables appear which must be stored in tabular form for the application of Milne's integration formulas. Accordingly, storage assignments in the *704* core storage must be made for the tables d^2x/dt^2, dx/dt, and x. As mentioned before, these tables will occupy eight words each, and the variable expressed by each table will be addressed by the location of the first word of the able. Suppose that the table locations are selected as follows:

x:3000 (3000 through 3007) (In what follows, all addresses and locations are expressed in the octal system.)

$\frac{dx}{dt}$:3010 (3010 through 3017)

$\frac{d^2x}{dt^2}$:3020 (3020 through 3027)

and assume the constant A is stored at location 3030. A *704* instruction routine can now be written which will accomplish the algebra implied by equation 2. Reference to a *704* "Manual of Operation" will clear up any question regarding the function of the following instructions. Suppose the instructions of this routine are stored beginning at location 4000, as follows:

Location	Operation	Address	Result
4000	LDQ	3010	Get $\frac{dx}{dt}$ into multiplier register.
4001	FMP	3000	Form product $x\frac{dx}{dt}$ in accumulator.
4002	FSB	3000	Subtract x from accumulator.
4003	FAD	3030	Add A to accumulator.
So far, $x\frac{dx}{dt}-x+A$ has been computed.			
4004	STO	3031	A temporary storage location.
4005	LDQ	3031	Get sum in multiplier register.
4006	FMP	3031	Form square of sum.
According to equation 2 this quantity is $\frac{d^2x}{dt^2}$, therefore			
4007	STO	3020	Store result in location of $\frac{d^2x}{dt^2}$

The routine stored at locations 4000–4007 expresses the differential equation which is being solved by expressing the highest order derivative in terms of the rest of the equation. The solution routine will be complete when the high-order derivative so computed is successively integrated to yield lower order derivatives. This is done by using the integration subroutine as shown in the following table.

Location	Operation	Tag	Address	
4010	TSX	(4)	5500	Enter the integration subroutine.
4011		3010	3020	Which variables to use.

The instruction at address 4010 causes the program to interrupt its normal sequence and to transfer control to the first instruction of the integration routine, at 5500. The location 4011 contains two addresses which the integration subroutine requires. The left address (in the "decrement" part of the word) 3010, is the location of integral function, dx/dt, and the right address 3020 is the location of the integrand function, d^2x/dt^2. The Milne formula will be applied to the proper numbers appearing in the two tables specified, and the value of the integral computed will be placed in the table at 3010. The number at 3010 is thus the "current" value of the function dx/dt. After completing this computation, control is transferred back to location 4012, and the next instruction is taken from there. The previous sequence must be repeated to obtain x from dx/dt, so

Location	Operation	Tag	Address	
4012	TSX	(4)	5500	Enter integration subroutine.
4013		3000	3010	Which variables to use.

This time the integrand is the previously computed dx/dt and the integral is x, which is placed in the table at 3000, becoming the "current" value of x. The instructions written so far complete the mathematical portion of the routine to solve equation 2.

For the process to begin and proceed properly, it is necessary to store at locations 3000 and 3010 the initial values of the variables x and dx/dt, respectively. The execution of the instructions 4000 to 4007 will compute the initial value of d^2x/dt^2 and the instructions 4010 to 4013 will predict the next values (at $t_0 + \Delta t = t_0 + h$) of x and dx/dt.

The next step in the program could be to print the values of the computed functions. A subroutine is provided for this purpose which has the ability to print an unlimited number of quantities, six to a line, in floating point decimal notation. It would be desirable to print the independent variable t, d^2x/dt^2, dx/dt and x.

Thus:

Location	Operation	Tag	Address	
4014	TSX	4	5000	Enter printing subroutine
4015	7612		3020	Location of t; $\frac{d^2x}{dt^2}$
4016	3010	1	3000	Location of $\frac{dx}{dt}$; x

In the locations following the TSX instruction are placed the addresses of the quantities to be printed. Two addresses are placed in each word. To indicate which pair is the last, a tag of 1 is placed in that location. Execution of the instruction at 4014 causes control to be transferred to the printing subroutine (5000) and the specified quantities are translated from floating binary to floating decimal and printed. Then control is returned to the location following the location of the last pair of addresses to be printed. Any number of pairs of addresses may follow the TSX at 4014, however, the last pair must always be identified by a tag of 1. The printing subroutine functions as described upon its first entry (that is, the first time the instruction at 4014 is executed) however, on subsequent entries, it may or may not print depending upon whether the solution has reached a "printing point." To avoid the printing of excess data, the printing subroutine will ignore all entries that are not coincident with a prescribed printing interval. The printing interval is a quantity that must be stored in location 7603 before starting the program. In this example problem, a suitable printing interval might be 0.1 second, therefore, 0.1 should be stored at location 7603.

The last step to complete the program for the solution of equation 2 is to cause the advance of the independent variable t to its next value, $t_0 + h$. This implies that all the variable tables must be shifted, as required by the fact that the integration routine is producing new values of each function for which space must be provided. These two operations, as well as others, are taken care of by the up-date routine, which is entered thus:

Location	Operation	Tag	Address	
4017	TSX	4	7200	Enter "up-date"
4020	3000		3010	Variable table addresses.
4021	3020	1	0000	

After the up-date entry TSX, the addresses of each variable table are given so that these tables can be shifted. The tag of 1 appears in the last word for reasons discussed, in connection with printing. Having completed all the operations required to solve the equation, the final instruction serves to return the program to the original instruction, at 4000, so that the process repeats itself:

Location	Operation	Tag	Address	
4022	TRA		4000	Return to beginning.

Consider the over-all action of the program stored from 4000 to 4022. When the execution begins, the initial conditions are used to compute the high-order derivative. Then the integration routine predicts the value of the lower order derivatives for $t = t_0 + h$. This is termed a prediction pass. At the end of a prediction pass, the up-date routine advances the independent variable to $t_0 + h$ and shifts the tables. The control then returns to 4000 and a corrected value of the high-order derivative is computed from the predicted values of the lower order derivatives. From this corrected high-order derivative, corrected values of the lower derivatives are "integrated." This is termed a correction pass. Throughout the solution of the equation correction passes are alternated with prediction passes, each pass, of course, using the same instruction loop. At the end of a correction pass, the up-date routine compares the results of the two passes and determines how closely the computed values agreed. For this purpose an initially stored value of allowable error (place at 7604) is used. If the predicted and corrected value for any integration did not agree within the amount of this error, the integration interval is restored to a very small, starting value. If the predicted and corrected values for all integrations were closer than 1/100 of this error, then the integration interval is doubled to allow greater computation speed. This is done automatically by the up-date subroutine and the necessary changes in the variable tables to effect the interval change are taken care of.

The magnitude of the allowable error to be used can be determined by consideration of accuracy required in the solution. If only three decimal digits are desired in the results, an allowable error of 10^{-3} or 10^{-4} should suffice. As the magnitude of the allowable error is reduced, the solution time required will, of course, increase because integration will proceed with a smaller interval in the independent variable.

The interval of integration can be doubled as often as is permissible, however its size will not be allowed to exceed the printing interval, so that no printing interval will be skipped.

Simultaneous Differential Equations

If several simultaneous differential equations are to be solved, the procedure to follow is similar to that used for the example. Each equation should be solved for its highest order derivative. If the high-order derivative appears in more than one equation, it may be possible to eliminate the derivative and reduce the number of equations. The ideal situation is obtained when the coupling between equations is by lower order terms only.

If this form can be obtained, then all the algebraic operations for all the equations can be done in the first portion of the solution loop, followed by integration of all the derivatives in each equation.

If some coupling between equations is by highest order derivative, then the equation having this derivative as its left member must be summed first in the algebra so that the derivative can be used to form other equations in the group.

Table Look-Up

Suppose that in the equation to be solved, a term such as e^x had appeared. The easiest way to handle this would be to make use of the table look-up subroutine provided in NIDA. At some point in the algebraic portion of the solution loop the value of this function would be required and could have been obtained thus:

Location	Operation	Tag	Address	
4005 (say)	TSX	4	6100	Enter table look-up.
4006	4100		3000	e table; x

The location following the TSX instruction contains two addresses required by look-up. The left address indicates where the table of values of the exponential function is stored and the right address is the location of the argument whose function is to be found in this case x. The look-up routine fits the table of values with a seventh order polynomial, and interpolates from this. When the control is returned to the main loop at 4007, the value of e^x appears in the accumulator and must be used or stored at that time. The machine will stop to signal an error if an attempt is made to extrapolate the stored table. The table of values of the function stored beginning at 4100 must have the following form:

Location

4100 : The tabular interval (floating binary).
4101 : The number of tabular entries in fixed binary with the binary point considered to follow position 35 of the word.
4102 : The value of the argument corresponding to the first entry in the table (floating binary).
4103 : First tabular entry (floating binary).
4104 : Second tabular entry, etc.

Table I. Summary of Nida Linkage Conventions (Octal)

	$q+i$: $L(r)$		$L(s)$
	$q+i+1$:Return		

Initial conditions for all variables are stored in the first table location.
Independent variable is stored at location 7612.
Permissible error is stored at location 7604.
Printing interval is stored at location 7603.
Store first instruction of main program at location 4000.
Start operation by transferring to location 7700.

Loading Information

The instructions comprising NIDA are contained in 63 binary cards and may be loaded with any absolute binary loader. NIDA occupies storage locations 5000 to 7777. The instructions of the solution loop may be punched and loaded in any way desired. All computations in the NIDA system are done in floating binary, consequently the data must be so loaded and the solution loop must use floating point arithmetic when dealing with these data.

The solution loop instructions must be arranged so that location 4000 is the first instruction to be executed. After loading all instructions and data, start by transferring to 7700.

The NIDA routines are also available in symbolic form.

Speed

The approximate execution times for the NIDA subroutine are as follows:

Integration = 3.66 milliseconds per integration per variable. This includes both prediction and correction
Up-dating = 2.74 milliseconds per interval (includes functions following both prediction and correction passes)
Table look-up = 7.5 milliseconds per use

Thus, in the foregoing example, the approximate time required per integration interval would be about:

2 integrations at 3.66	= 7.32
1 up-date at 2.74	= 5.48
Main loop instructions (approximate)	= 0.7
	Total 13.5 milliseconds per point

Printing is done at 150 lines per minute, interspersed with the computation.

A summary of NIDA linkage conventions is given in Table I.

Summary

This paper has described a convenient and time-saving method of integrating differential equations using the 704 EDPM. The method is applicable to all ordinary equations of arbitrary order, linear or not. An example was given which it is hoped was sufficiently explicit to instruct interested persons in the use of the system.

Appendix. Milne's Method for Solving Differential Equations

The method of Milne selected for solving a differential equation requires that four starting values of the function sought are known. How to obtain these starting values will be discussed later. To proceed with the explanation, let it be assumed that the problem is to find a particular solution of

$$y' = f(x,y) \tag{3}$$

say, the solution passing through (x_0, y_0). Let it be further assumed that one has found the values of y for $x = x_0 + h$, $x_0 + 2h$, and

x_0+3h. Milne's method for extending the solution consists in finding y for $x=x_0+4h$ by the equation (predictor)

$$y_4=y_0+\frac{4h}{3}(2y_1'-y_2'+2y_3') \qquad (4)$$

where

$$y_i=y(x_0+ih)$$

and

$$y_i'=f(x_0+ih,\ y_i)$$

$$i=1,\ 2,\ 3,\ 4.$$

The values of y_1', y_2', and y_3' are computed by substituting (x_1, y_1), (x_2, y_2) and (x_3, y_3) into equation 3. Next one obtains y_4 by equation 4 and then y_4' by substituting (x_4, y_4) into equation 3. The values of y_4 and y_4' thus found are tentative values of y and y' corresponding to $x=x_4=x_0+4h$. These values are then checked by the equation (corrector)

$$y_4=y_2+\frac{h}{3}(y_4'+4y_3'+y_2) \qquad (5)$$

Equations 4 and 5 obtain from the following relation

$$\int_{y_i}^{y_n} dy=\int_{x_i}^{x_n} y'dx$$

or

$$y_n=y_i+\int_{x_i}^{x_n} y'dx \qquad (6)$$

by replacing the integral with an approximate integral. In particular the approximation is achieved by assuming that y' is a polynomial. The error in equation 5 may be shown to be

$$\frac{-h^5}{90} f^{(4)}_{(u)} \qquad (7)$$

where u is some number between x_0 and x_0+4h. The error in equation 4 is

$$\frac{28}{90} h^5 f^{(4)}_{(v)} \qquad (8)$$

where v lies between x_0 and x_0+4h.

In the application of Milne's method, the exact values of the error of equations 7 and 8 cannot be computed since, in general, the function of x representing y' is not known. Further, the derivations of these error equations fail to stipulate the precise values of u and v. When $f(x)=y'$, the error equations 7 and 8 become

$$\frac{-h^5}{90}\times\frac{d^5y}{dx^5}$$

and

$$+\frac{28h^5}{90}\times\frac{d^5y}{dx^5}$$

respectively. The fifth derivative under ordinary circumstances remains essentially constant over the interval from x_0 to x_0+4h. Accordingly, the difference between the values for y_4, as given by

$$y_{4p}=y_0+\frac{4h}{3}(2y_1'-y_2'+2y_3') \qquad (9)$$

and

$$y_{4c}=y_2+\frac{h}{3}(y_2'+4y_3'+y_4') \qquad (10)$$

is

$$\frac{29h^5}{90},\ \frac{d^5y}{dx^5}$$

One twenty-ninth of this is the error in y_4 as given by equation 7. It is clear that the ratio of error may be defined as

$$\frac{2}{29}\left[\frac{|y_{4p}-y_{4c}|}{|y_{4p}|+|y_{4c}|}\right]$$

Experience dictates that this is too optimistic and that a more accurate result obtains by replacing 29 with the divisor 10. Thus one may define

$$\text{Ratio of error}=E=0.2\,\frac{|y_p-y_c|}{|y_p|+|y_c|} \qquad (11)$$

If equation 11 is significant, Milne's method may be continued with a smaller value of h. For example, if one halves the value of h, calling the last four established y-values y_0, y_1, y_2, y_3, one needs the values designated by $y_{3/2}, y_{5/2}$, viz., the values corresponding to

$$x=x_0+\frac{3h}{2}$$

and

$$x=x_0+\frac{5h}{2}$$

By applying equation 6

$$y_{5/2}=y_2+\int_{x_2}^{x_2+\frac{h}{2}} y'dx$$

and

$$y_{3/2}=y_1+\int_{x_1}^{x_1+\frac{h}{2}} y'dx$$

Replacing y' by a polynomial and performing the integration one obtains

$$y_{5/2}=y_2+\frac{h}{384}(7y'_{-1}-37y'_0+197y'_1+25y'_2) \qquad (12)$$

As mentioned previously, the Milne method requires the possession of four consecutive points on the curve before it can be started. In the same manner that the Milne method finds a fifth point on a curve, given four points, one can find a second point given one, a third point, given two, and a fourth point, given three. This is accomplished by applying equation 6. y' is replaced by a polynomial. The order of the polynomial increases as one advances along the curve. The starting formulas obtained in this manner are as follows, with the estimated error given in the right-hand column:

Integration A $y_{1p}=y_0+hy_0' \qquad \frac{h^2}{2}y''$ (13)

Integration B $y_{1c}=y_0+\frac{h}{2}(y_0'+y_1')-\frac{h^3}{12}y'''$ (14)

Integration C $y_{2p}=y_0+2hy_1' \qquad \frac{h^3}{3}y'''$ (15)

Integration D $y_{2c}=y_0+\frac{h}{3}(y_0'+4y_1'+y_2')-\frac{h^5}{90}y^{(5)}$ (16)

Integration E $y_{3p}=y_0+\frac{3h}{4}(y_0'+3y_2') \qquad \frac{3h^4}{8}y^{(4)}$ (17)

Integration F $y_{3c}=y_0+\frac{3h}{8}(y_0'+3y_1'+3y_2'+y_3')-\frac{3h^5}{80}y^{(5)}$ (18)

Equations 4 and 5 of Milne's for extending the solution may be referred to as integration G and integration H, respectively.

A Field Survey of Transformer Oil Quality

W. J. DEGNAN
MEMBER AIEE

E. J. SHIMANSKI
NONMEMBER AIEE

REDUCTION of power transformer insulation by the recently recommended two full basic insulation levels[1] has placed renewed emphasis on oil quality. The design of corona-free transformers has eliminated the use of sharp-edged electrodes in highly stressed locations, favoring the more uniform dielectric field conditions. Because contamination in these uniform fields has a much greater influence on dielectric strength that in nonuniform fields, the question of oil quality is of further importance.

Not only must the transformer oil be of high quality during factory tests but it is essential that it does not degrade under service conditions or, if degradation eventually exists, some means must be available to determine the point at which preventive maintenance steps must be taken. If transformer oil meets these requirements, then the full cost-saving advantage of the reduced insulation can be realized.

To determine the quality of oil in transformers that have been in service for long periods of time, it was decided to conduct a nation-wide survey of many such transformers. The regions of the country and types of transformers selected were such that the results obtained are representative of large power transformers located anywhere in this country or in similar climatic regions. The regions correspond to the eight areas indicated numerically on the map shown in Fig. 1. The units sampled were all General Electric Company power transformers in actual service for periods up to 17 years. The transformers were generally well-loaded units rather than those "idling" on the line and were rated 115 kv and higher with a minimum of 10,000 kva. A variation in oil-preservation methods was obtained with three of the basic types being utilized in present-day design of power transformers (conservator, gas-oil-sealed, and automatic gas-sealed). Typical modes of cooling were also represented in the units (self-cooled, forced-air-cooled, forced-oil-cooled, and a few water-cooled). Within these limits, the units were selected at random. All sampling was conducted during the fall and winter of 1955.

Sampling Technique

A preliminary study was conducted locally as a pilot operation to provide information on techniques to be utilized in the broader investigation, one outcome of which was the development of a reliable outdoor sampling technique for large transformers.

Of primary concern were the containers into which the samples were to be drawn. It was found necessary to provide clean, new-oil-filled containers from the central testing laboratory (Pittsfield) to insure uniformity and eliminate the possible influence caused by a doubtful sample bottle condition. Each unit was sampled from the bottom sample valve into two 1-quart amber-glass bottles provided with a foil-lined cap. The clearest picture of the sampling technique can be given by listing the procedure as outlined in the instructions to the field representatives:

1. Do not sample on very cold days or during rain, snow, or fog.
2. Sample only from units with a bottom valve and sampling valve. Do not use the main opening in the valve.
3. Wipe the sampling valve thoroughly with a clean, dry cloth.
4. Bleed off 1 quart of oil into a separate container and discard.
5. Empty two of the 1-quart bottles which were shipped oil-filled and fill each half full of oil directly from the sample valve; shake and discard. Fill half full again, shake and discard.
6. Fill each of the two bottles to the height of the neck and allow oil to impinge on the wall of the bottle. Cap tightly with the foil-lined screw cap provided.
7. Sample units with up to 20 years of service.

Field data were also accumulated to determine the history of the unit and its oil with particular emphasis on any filtration or reconditioning of the oil.

Oil Tests and What They Signify About Oil

A very concise description of the various electrical, physical, and chemical tests usually employed in evaluating insulating oils has been set up in the unpublished report by the Subcommittee on Insulating Fluids of the AIEE Committee on Transformers. This guide quite adequately describes the tests and, therefore, a verbatim inclusion of their descriptions is made in this paper. Added to the discussion are comments regarding the ASTM (American Society for Testing Materials) dielectric strength tests and the entire sections on the water content test and the use of the VDE (Verein Deutscher Elektrotechniker) test electrodes. All tests in this survey conformed to the following outlined procedure. Reference to the ASTM number will provide a complete description of each test.

DIELECTRIC STRENGTH

ASTM Test (ASTM D-877)

"The dielectric strength of an insulating oil is the average voltage gradient at which electrical failure or breakdown occurs under prescribed conditions. This test is made to determine if an oil has adequate electrical strength and is not necessarily an indication of its other properties."

A low dielectric strength is indicative of the presence of contaminating agents such as water, dirt, or conducting particles. The true significance of a dielectric strength value depends upon how closely it is a reflection of conditions within the transformer being tested as well as upon the actual stress that will be applied to the oil in the unit. Generally a dielectric strength of over 22 kv is considered acceptable for used oils.

The VDE Test Electrodes

The testing of oils for dielectric strength by means of more uniform field electrodes, and particularly the spherical surfaced VDE type, is more specifically the topic of a paper[2] which describes another portion of the broad program dealing with oil serviceability. That work shows the more uniform field gap to be more sensitive to those factors influencing oil strength and, therefore, a better criterion than the previously used nonuniform electrodes

*OA = self-cooled, FA = forced -air-cooled, FOA = forced-oil-air cooled, FOW = forced-oil-water-cooled, and WC = water-cooled.

†C = conservator, GS = gas-sealed, GOS = gas-oil-sealed, and S = sealed.

‡PPM = parts of water per million of oil, by weight.

Power Factor (ASTM D-924)

"Power factor is the ratio of the power dissipated in the oil in watts, to the product of the effective voltage and current in volt-amperes, when tested with a sinusoidal field under prescribed conditions. It is usually measured at 25°C and reported as per cent power factor measured at 60 cycles corrected to 20°C. This test is an indication of the presence of contaminants or deterioration products such as water, oxidation products, metal soaps, charged colloids, etc."

Resistivity (ASTM D-257)

"The volume resistivity in ohms centimeter of an oil is the ratio of the d-c potential gradient in volts per centimeter paralleling the current flow in amperes per square centimeter at a given instant of time and under prescribed conditions. A low resistivity normally indicates the presence of conductive contaminants but has not been widely applied to used oils."

Water Content

A Karl Fischer electrometric technique previously described[3] was utilized to determine the water contents in this study. This method is presently under consideration as an industry standard by the ASTM for determination of water content of insulating liquids. Water is detected by an electrometric circuit that allows a determination to within ±2 parts of water per million parts of oil by weight.

Acidity or Neutralization Number (ASTM D-664 and D-974)

"Neutralization number for used oils is in general a measure of the acidic constituents of an oil and is the milligrams of KOH required to neutralize one gram of oil. It is a measure of the oil deterioration and some types of contamination."

Color (ASTM D-155)

"The color of an insulating oil is determined by means of transmitted light and is expressed by a numerical value based on comparison with a series of color standards. A rapidly increasing or high color number is an indication of oil deterioration or contamination or both."

Viscosity (ASTM D-88 and D-445)

"The viscosity of an oil is its resistance to uniformly continuous flow, without turbulence, inertia, or other forces. The viscosity of insulating oil is usually measured by the time of flow of a given quantity of oil under controlled conditions. Viscosity is not significantly affected by oil contamination or deterioration but may be useful for identifying certain types of used insulating oils."

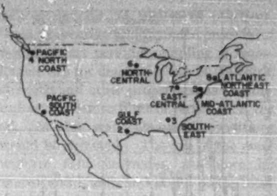

Fig. 1. Sampling regions for field oil survey

Interfacial Tension (ASTM D-971)

"The interfacial tension between an electrical insulating oil and water is a measure of the molecular attractive force between their unlike molecules at the interface. It is expressed in dynes per centimeter. This test provides a means of detecting soluble polar contaminants and products of deterioration."

Results

The results of all chemical, physical, and electrical tests for the 71 transformers are compiled in Table I, arranged by geographic region. The data of primary importance are shown in Figs. 2 through 9, where each symbol plotted represents the average value; the lines extend to show the range between minimum and maximum values. A survey of the data shows no noticeable effect on the properties because of geographic location or type of transformer cooling. Some properties are affected by the method of oil preservation and age of the oil.

Fig. 2 shows that dielectric strength, the most important property, when measured by the VDE cell, is not affected by the age of transformer oil, nor can any trend be seen owing to the type of preservation used. Similarly, no trends can be detected when the ASTM test cup is employed; see Fig. 3.

The water content of the transformer oil is not affected by oil age or method of preservation; see Fig. 4. Of particular importance is the fact that the water content did not exceed 22 parts per million on any unit.

The power factor data, Fig. 5, show a slight increase caused by age and no consistent difference is evident for the different types of preservation. Resistivity of the oil, however, shows a corresponding decrease with oil age, Fig. 6, and, again, all methods of preservation appear to give similar results.

Interfacial tension, as shown in Fig. 7, decreases with age, more in the early years than later, but no effect of type of preservation is noticeable. Similarly, color increases slightly in the first few years, leveling off at a value of approximately two; see Fig. 8. No influence of preservation is seen.

The acidity appears to increase with increased oil life, as shown in Fig. 9. The conservator units appear to have very slightly higher values of acidity, although all values are well below that considered to be acceptable on new oil.

It is interesting that the oil in only six transformers had been filtered and none had been reclaimed during the operating experience of the 71 units. No time pattern or reason was evident in the filtration (units were filtered after an oil life ranging from 4 to 13 years). Table II summarizes the maximum (or minimum) property values obtained on all units and on 95 per cent of all units.

Table II. Summary of Oil Property Value

Property	Minimum Value for All of Units	Minimum Value for 95 Per Cent of Units
VDE dielectric stress, kv rms	36.8	44.4
ASTM dielectric stress, kv rms	23.8	30.8
Interfacial tension, dynes per centimeter	22.0	23.6
Resistivity, 25 degrees centigrade, 10^{11} ohms-centimeter	6.3	9.2
	Maximum Value for All of Units	Maximum Value for 95 Per Cent of Units
Power factor, 25 degrees centigrade, per cent	0.40	0.2
Water, parts per million	22	18
Acidity, milligrams KOH per gram	0.051	0.045
Color (ASTM)	$2^1/_2$	2

Significance of Results

The tests described are those which are generally used to evaluate the serviceability of insulating oils in use in a wide variety of applications. Even when thinking is restricted to transformer applications, the demands placed upon the liquid vary considerably with specific applications and individual power company criteria. In view of this, it is difficult to set arbitrarily maximum or minimum values for the various oil characteristics normally evaluated to determine the continued serviceability of oil in use. It is possible, however, to recognize certain practical limiting values and, in at least one instance, it is possible to cite an acceptable range of values.

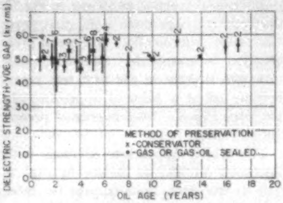

Fig. 2. Effect of transformer oil age on dielectric strength, as determined by the more uniform field-type electrodes. Points are averages, lines indicate spread, and the number of units is shown. (This applies also for Figs. 3 through 9)

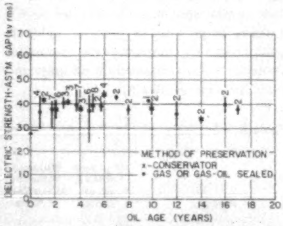

Fig. 3. Effect of transformer oil age on dielectric strength, as determined by ASTM electrodes

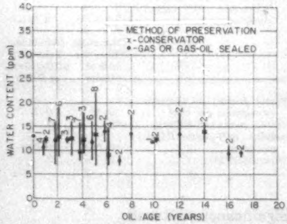

Fig. 4. Effect of transformer oil age on water content of oil

One of the more important criteria used by the power industry to maintain oil in acceptable condition is the ASTM dielectric strength test. Although there is no unanimous agreement on the limiting serviceability values determined by this test procedure, a wide segment of the industry considers a value of 22 kv or higher as indicative that the oil does not need reconditioning or treatment in so far as breakdown strength is concerned. As indicated in this survey, every one of the units exhibited an ASTM dielectric strength value well above 22 kv. In fact, for this oil characteristic alone, all but one of the oils tested would meet a minimum dielectric strength value of 26 kv, which meets the new oil specification of most of the industry. It is interesting to note that 95 per cent of the values reported here have electrical strengths greater than 30 kv.

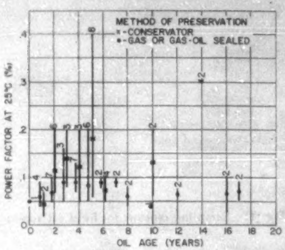

Fig. 5. Effect of transformer oil age on 60-cycle power factor

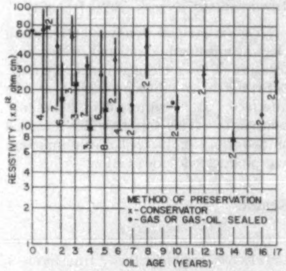

Fig. 6. Effect of transformer oil age on resistivity

In discussing other pertinent electrical, physical, and chemical characteristics which are determined on oils in service, it must be recognized that no single oil characteristic at the present state of knowledge can be relied upon as the sole criterion of oil serviceability. Because of the variety of application conditions, transformer types, the growing trend toward preventive maintenance, and the interdependence of some of these oil tests, it is almost impossible to select a limiting value for any one oil characteristic which would be applicable in all cases. Of greater significance is the evaluation of the general picture established by all pertinent oil characteristics. An estimate of continued serviceability can be intelligently made in any specific case only if the information obtained is focused in terms of the actual unit being considered—its design, rating, age, history, loading, preservation means, and other factors known to the operator.

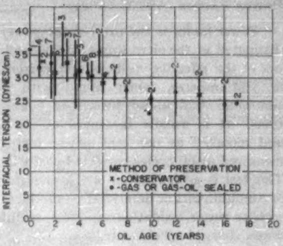

Fig. 7. Effect of transformer oil age on interfacial tension

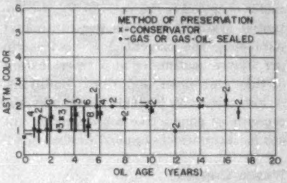

Fig. 8. Effect of transformer oil age on ASTM color

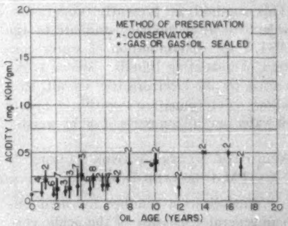

Fig. 9. Effect of transformer oil age on acidity

For the purpose of the present investigation, which deals specifically with larger power transformers embodying three methods of oil preservation, a critical study of the results in Table I indicates beyond doubt that the over-all oil quality of the 71 units surveyed is exceptionally good even by some of the more stringent criteria employed by many utilities. In light of the discussion given earlier, it is felt that these oils can undoubtedly be classified as being in satisfactory condition for continued use. In addition, the data obtained do not indicate that the oils have been seriously affected by the general lack of oil reconditioning nor should any limitation be placed upon their continued use.

Conclusions

The reported survey of oil quality in 71 power transformers reveals that the dielectric strength and all other oil properties are unaffected or only slightly affected by use for periods up to 17 years. Location within the country and type of cooling appear to have no effect on the oil properties, but some properties remain slightly better when preservation is accomplished by gas-sealed or gas-oil-sealed methods.

The effectiveness of the modern oil preservation systems in maintaining the quality of the oil in the transformers studied is emphasized by the apparent lack of periodic oil treatment practices. Good preventive maintenance procedures would dictate periodic sampling of transformer oils for determination of dielectric strength and other properties, as an indication of when to filter or recondition the oil. In this way, abnormal conditions would be detected. The use of the more uniform field electrodes, as shown by Weber and Kaufman,[2] would be the more desirable method for the dielectric strength determination.

The excellent behavior of these oils in use for periods up to 17 years indicates that very little or no extra effort or expense would be required to maintain transformer oils in high-quality condition over extended periods of time, and that degradation of oil in service is not a limiting factor in utilizing the cost-saving advantages of insulation reduction of two full levels.

Discussion

L. Wetherill (General Electric Company, Pittsfield, Mass.): The outstanding conclusion which the authors have shown is that oil in power transformers with modern oil preservation features such as automatic gas seal or conservator construction retains very good quality for a great many years. It is reassuring to see a sufficient statistical study to demonstrate that oil is being maintained in quality so well in power transformers. This furnishes a sound basis for concluding that transformer oil can be and generally is maintained in suitable condition for insulation levels reduced two steps. Other factors must, of course, be considered in each specific case before the suitability for insulation level reduced two steps can be determined.

While the authors survey a number of different oil characteristics, perhaps the dielectric strength obtained with the VDE-type electrodes is of outstanding significance in its bearing on the paper by Weber and Kaufman (see reference 2 of the paper) dealing with the development of this same gap.

One of the two primary functions of the oil in a power transformer is to withstand dielectric stress and most of the tests which are used in evaluating oil are aimed directly or indirectly at measuring the ability of the oil to withstand dielectric stress and to continue withstanding dielectric stress. It has always seemed a little surprising that in evaluating the dielectric strength of oil, measurement of dielectric strength has played such a small part and measurement of so many other characteristics has been found necessary. An extreme view which has been expressed sometimes is that the dielectric strength of the oil is the one characteristic which does not have to be measured because the other tests customarily made on oil are more sensitive indicators of suitability of oil for use in transformers than the dielectric strength test. The data presented by the author throw no light on this situation, but the paper by Weber and Kaufman indicates that if the test results obtained on the VDE-type gap are considered the situation is considerably changed, since the dielectric strength measurements are indicative of dielectric strength as demonstrated in a transformer. This should remove some of the present dependence on other tests to indicate quality of insulating oil.

The authors are to be congratulated on having added to our understanding of dielectric strength characteristics of oil in service and how it is best measured. It is to be hoped that others will conduct investigations in this same area so that the industry can benefit through proper utilization of a rounded contour test gap.

W. J. Degnan and **E. J. Shimanski**: We are grateful to Mr. Wetherill for his comments. The finding that modern oil preservation methods allow successful maintenance of transformer oil quality has led to further study.

About 5 years ago 12 transformers were constructed which incorporated insulation reduced two levels; these units have been in successful operation since that time. An oil survey of these transformers has been conducted since preparation of this paper. Tests, identical to those covered in the paper, were made on samples from these units and in all cases the values obtained were in complete agreement with the data presented in the paper.

This is added evidence that degradation of oil in service is not a limiting factor in reducing insulation two insulation levels.

Some of the Engineering Aspects of the Machine Translation of Language

ROBERT E. WALL, JR.
ASSOCIATE MEMBER AIEE

THE MECHANICAL translation of language by digital data-processing equipment was first suggested in private correspondence between A. D. Booth and W. Weaver in 1946.[1] Since that time, others have been attracted to the field of mechanical translation and their work has resulted in the publication of a magazine, a book, and numerous papers.[2,3,4]

At the time that mechanical translation was conceived by Weaver and Booth, the necessary computer components were not available to realize a mechanical translator. In this paper it will be shown that the recent advances in computer technology have made mechanical translation a definite possibility provided certain limitations are made in the type of material which will be fed into the machine, and also if certain allowances are made in the required quality of the output material.

The intent of this paper is to acquaint engineers with the general "state of the art" of the machine translation problem and to indicate some of the more promising methods of attack on the individual problems. The individual problems are not considered in detail. A careful analysis of either the coding problem or the memory requirements would require more space than is used for this entire paper. Detailed discussions will be handled in subsequent papers.

General Considerations

The people of every highly civilized speech community have a rich literary heritage. It would not seem reasonable to expect the first translating machines to translate this literature from one language to another and to preserve completely the original style and the more delicate shades of thought and meaning. There is, however, a very heavy demand for translations of scientific material at present. Since scientists tend to use a simple language structure in their writing, and since readers of scientific material are interested mainly in the intelligibility of the material, it is possible to make many useful restrictions on the amount of processing which a machine translator would have to perform if the input is restricted to scientific writing. For example, it has been shown[5] that Russian scientific writers tend to follow English word order form. It is likely that a machine translator can produce satisfactory Russian-English translations without rearranging word order in the "target" language. The "target" language is defined as the language into which the translation is made, while "source" language refers to the language from which the translation is made. The fact that only intelligibility in the output material is required allows a considerable number of restrictions in the number of target language words stored in the dictionary. For example, a Russian-English dictionary[6] lists with the word "окаянство" the English equivalents "impiety, impiousness, ungodliness, godlessness." Nothing essential to understanding would be lost if only one of the four equivalents were stored. It might also be advisable to simplify the spelling of English words to decrease storage space, for example by storing "thru" instead of "through."

It seems unlikely that the quality of the translations from a machine would be equal to that supplied by a well-trained human translator. The machine would have to justify its existence by superiority over the human in speed and, if possible, by a lower per-word cost of translation. A language translation machine would undoubtedly represent a very large investment since it would require a large temporary storage space to allow the necessary processing of material, and it would have to have a permanent memory with a very large capacity and a relatively low access time. It seems likely that such a machine will cost as much as a modern large-sized digital computer which has a per-hour cost of about $250. Human translators will produce rough, understandable translations for a per-word cost of about one cent. This means that a $250-per-hour machine would have to produce about 25,000 words per hour or, in round numbers, about ten words per second, in order to have the same per-word cost. This figure is, of course, somewhat arbitrary, but it is certain that 1 word per second is too slow, and 100 words per second is probably faster than necessary.

Translation Process

Four definite steps are required in the translation process: encoding, memory search, logical operations, and decoding. Consider these four steps in order.

ENCODING

Two basic problems arise when an attempt is made to encode text material into the machine language, or "code." The first problem is that of the optimum selection of the machine code, and the second is that of transcribing printed text material into machine code. Printed material could be converted into machine code in many ways. Operators might transcribe the text material onto punched or magnetic tape; an electronic tape reader could then read the tape and supply the necessary electrical pulse patterns to the machine. As another possibility, the duties of the human transcriber and the mechanical tape reader might both be performed by an all-electronic device. A machine has been recently announced which will read and encode English at the rate of 3,600 words per minute.[7] It should be possible to modify this machine so that it will read and encode the Russian Cyrillic alphabet. It is beyond the scope of this paper to discuss the configuration of an electronic encoder in detail; however, such a device is very important for the realization of economical machine translation since human transcribers who know only English would copy foreign language material slowly and there would be a high probability of error.

The machine code should be selected in such a way that the code groups were of uniform length, and so that storage of material would require the least number of bits. It appears that it is necessary to provide both capital and lower-case letter codes in order to process the material properly. The total requirement for Russian will then be about 80 distinct code groups: 9 for the number codes, about 10 for punctuation marks, and 61 for letter codes (5 of the 33 Russian letters never start a word and will not

need to be capitalized). A demand for 80 distinct code groups would seem to require a 7-bit code, but it will be shown that a basic 5-bit code may be made to yield 80 distinct code groups and, if properly selected, the 5-bit code will result in a considerable saving in storage. An example of such a basic 5-bit code is displayed in Table I. To test this code a random sample of a half-page of Russian text was analyzed; the occurrences of the various symbols are listed in Table II. The sample had a total of 786 symbols. Coding this material with a 7-bit code would require 786×7 totals 5,502 bits. If the code shown in Table I were used, there would be 745 occurrences of 5-bit codes and 41 occurrences of 10-bit codes; see Table II. The total number of bits required would be $41\times10+745\times5=4{,}135$ bits, or an average of $4135/786=5.23$ bits per symbol. Thus a considerable saving in storage space results from using this modified 5-bit code over that required with a 7-bit code.

Many other codes could be devised. The illustrated code does have a uniform code-group length. It was shown that a random sample of text could be coded with an average code length per symbol of only 5.23 bits; this is only 75 per cent of the bits required with a 7-bit code.

MEMORY SEARCH

The permanent memory system of the mechanical translator must store essentially all source language words except for those words (internationals) shared by the source and target languages. The permanent memory must also store essentially all source language word sequences (idioms) which do not give understandable word-for-word translations into the target language. Each source language entry must have the necessary target language equivalents stored with that entry in the memory. During the memory search, incoming text words may be compared with the source language entries in the memory, first in groups of words, with the idiomatic memory, then by single words, with the individual-word memory.

It has been shown[8] that words of rare occurrence must be translated, since very often these words determine the meaning of the whole sentence. Therefore, it would seem necessary to store the complete source language-target language dictionary, with the exception of internationals. The largest German-English dictionary[9] contains approximately 400,000 entries. When the selection of English equivalents is made it should not be necessary to store more than an average of two equivalents for each source langage words. If internationals are not stored, the total storage requirement is probably about 1,000,000 words. A reasonable estimate of the average length of a word would be 7 letters, or a little more than 35 bits using the code of Table I. The individual-word memory would thus contain about 40 megabits of information. The storage requirement for the idiomatic memory is considerably less, definitely not over 60,000 words in total.

The Russian language does not have as many words as either German or English but the storage requirements are probably about the same because in Russian 59 word affixes[10] are used to denote the grammatical usage of a word. The Russian noun has six cases and may be either singular or plural, and an adjective must agree with the noun that it modifies both in gender (there are three genders in Russian) and in case.

The amount of material stored in the memory system should be kept as small as possible, and the material should be stored in the memory in such a way that the search may proceed in the most efficient manner. It is possible to decrease the amount of material stored in the memory by not storing internationals. Other schemes for decreasing dictionary size depend on reducing a word to simpler components, such as reducing a compounded word to the words of which it consists, or dissecting a word into a stem and an ending in the case of affixed words. Eliminating the storage of internationals presents no serious logical difficulties per se. If an incoming text word should not correlate with any of the source language words in the dictionary, the word could be printed out in its original form or in its target-language phonetic equivalent. It is necessary to make a provision for printing out uncorrelated words anyway, in order to take care of misspelled words. Routines which involve dissection schemes would give a considerable decrease in memory size, but they all pre-

sent logical difficulties in their complete form. For instance, if separate stem and ending dictionaries are provided, difficulties result from the many irregularities of language and the necessity of coordinating the two dictionaries. It would seem useful to break up a word into stem and ending within the individual dictionary entry by listing the word stem first then the endings along with the target language equivalents. An incoming text word may then be compared with a stored source language word starting with letters farthest to the left in the words. If correlation is established, the target language equivalents stored with the correlated ending are read out and stored to await further processing.

A scheme for dissecting compounds has been developed by Reifler.[11] If a word is not located in the dictionary, the letter at the end of the word is ignored and the remainder of the word is compared with the dictionary. If this remainder is not located, another letter at the end is ignored. This process is continued until the remainder is located or until all the letters have been used up. Then the machine starts to ignore letters from the front of the word and to compare the remainder with the dictionary as before. When a portion of an incoming word has correlated with a stored sequence, then the ignored portion of the word must also be compared with the dictionary. If letters are ignored from the front of the word, or if ignored portions of a word are to be compared, it often would be necessary to go to a part of the memory which is far removed from the place that was searched in the previous step. This skipping about in a large memory system is a very serious problem. Any word which could not be correlated with a word in the dictionary would have to undergo any compound dissection routine which was built into the machine; thus all misspelled words and internationals would have to be tested for compounding before they were printed out. Since about ten per cent of ordinary Russian scientific text is composed of internationals, the time consumed in attempts at compound dissection would probably be prohibitive. If only letters at the end of the word were ignored, the ignored portion has not been compared with the memory, and if the routine were halted when all the letters have been used up, then no appreciable skipping about the dictionary would be required. This much of the compound dissection scheme might be profitably used.

There are many possible variations for the order in which words might be stored in the dictionary. They might be stored first according to the length of the word, then alphabetically; the words might be stored first according to grammatical type, then alphabetically; or the storage might be completely alphabetical. Each of these systems has certain advantages, but complete alphabetization has one clear-cut advantage over all other methods; each word then has a unique address in the store determined by one criterion alone, the spelling of the word. In this paper, only complete alphabetization of the dictionary will be considered.

The permanent memory has two design limits: a maximum allowable access time, and a maximum allowable size. The maximum size of a large permanent memory is mainly determined by physical limitations; for instance, a memory using a photographic plate to store the information may be limited in size by the area of plate which can be scanned. If a particular memory of the photographic-plate type is capable of storing 50 megabits of information, the memory cost will be approximately the same whether it stores 50 megabits or 15. Access time is actually determined by the efficiency of the search routine. Thus it is sometimes better to store more material in order to realize a more efficient search routine. The first criterion for determining the amount of material which must be stored in the memory system is necessarily the linguistic requirements of the problem. Once the linguistic requirements are satisfied, the all-important criterion for determining size of storage, sequence of storage, and the method of coding the material is the effect of each on the access time into the memory. The physical configuration of the memory largely establishes the optimum storage sequence and the most efficient indexing procedure. A likely device for the large memory of the translation machine is an optical device[12] in which the information would be stored on a photographic plate and the plate scanned by a beam of light formed by a cathode-ray spot and focused by a lens. To store the required 40 megabits of information in a memory of this type there might be about 6,500 rows of about 6,500 bits each. This would give a total of 42.5 megabits of storage. The discussion of storage sequence and indexing will be confined to schemes applicable to this type of storage. A hypothetical portion of a photographic plate on which a part of a dictionary is stored is illustrated in Fig. 1. Actually the 1's would most likely be just spots on the plate and the 0's just a lack of a spot, but the representation shown is easier to comprehend.

It can be shown that it is important for the largest part of an incoming text word to be correlated first. For instance, if the source language is English, incoming text words should be compared with "manage" before "man," and with "indicated" before "in." For this reason the source language entries shown in Fig. 1 are stored in inverse numerical sequence in a row, i.e., the numerically largest code group in a particular row is stored to the extreme left of the row with its target language entries, then the numerically next largest source language code group, and so on. The entries in column *C* of Fig. 1 are indexing entries which will be explained later. The word codes are entered in the rows starting with column 1, first the source language word code and then its target language equivalents. In Fig. 1, row 3780 stores the code for "офталмоскоп" as its first source language word, and row 3779 stores "офицновый" as its first source language word, etc. The word which will serve as an example is "офеня" and it is assumed to be stored in columns 127–153 of row 3778.

If the incoming text word were "офеня," and no indexing scheme were used, the spot would move in a path traced by the solid line in Fig. 1. The circuitry enclosed by the solid line would be used in this case. In each row, in order, the spot would read the code until a binary place was reached which was different from the corresponding binary place in the text-word code. If at that binary place the text code had a "1" and the dictionary code had a "0," the spot would start to read the next row. If the reverse were true, the word must be located in that row if it is stored in the dictionary. The spot would continue reading that row until correlation was established or until a stored source language code sequence had a smaller code number than the text word, which would establish the fact that the text code was not stored in the dictionary. A dissection routine would then be started if such schemes were included in the stored logic. With this search procedure, the spot must read an average of perhaps three or four binary places at the beginning of each row before the machine could determine whether or not it should go to the next row or should continue to read the same row. An indexing scheme may be used to reduce the average number of binary places that are read in a row before the machine would decide whether or not it must go to the next row. This is particularly easy in this example since complete alphabetization of the dictionary is assumed.

The circuitry necessary for one possible indexing scheme is represented in block form in Fig. 1, enclosed in a dashed line. This scheme depends upon the fact that the first two letters of a word will determine closely the row in which the word must be stored. A "1" is placed in column *C* in a particular row each time the first two letters of the first word stored in that row are different from the first two letters of the first word stored in the previous row. The idea is to treat the first two 5-bit code groups of an incoming text word code as a binary number; the rows which start with "оф" (code 0111010100 which is binary for decimal 468) then form row group 468. For example, suppose that the incoming text word is "офеня" (peddler). The first two letters, "оф" will have the code 0111010100.

This code sequence is transferred to the reversible binary counter, leaving the contents of the register unchanged. The spot then moves down column *C*. subtracting a binary "1" (0000000001) from the counter each time the spot passes a "1" in column *C*. When the content of the counter is reduced to zero, the machine starts reading the rows, as indicated by the dashed line in Fig. 1, exactly in the same way as when no indexing scheme was used. Two complications arise in the scheme: first, the first row of the dictionary starts with 0000100100 (it is assumed that аГенЦ (lamb) is stored in this position), which is considerably larger than 000000001 and, second, some letter sequences do not exist as the first two letters of a word, for instance, there are no words beginning оу . . . . The first complication is resolved by the use of a subtractor between the input register and the counter which automatically subtracts a binary 0000100011 from the 10-bit sequence as it is transferred to the counter. If a negative difference is obtained when this subtraction is performed, the word must be located in the first row. If the difference is positive, the spot moves down column *C* subtracting 0000000001 from the contents of the counter each time it passes a binary "1." The second complication is resolved by placing dummy "1's" in column *C* in rows which have the same first two letters as the preceding row. For instance, alphabetically (and numerically for the corresponding codes) the sequences are "от, оу, оф," but no "оу . . ." words exist. Therefore, to keep the count straight a dummy "1" is placed in column 1, row 3777. The search for the word "офеня" would then follow the path shown by the dashed line. This path would require reading only one binary place per row until the spot had approached within an average of six or seven rows of the desired row.

About 1,200 words[13] constitute approximately 40 per cent of text material in most languages so it would seem profitable to include these words of short length and very high probability of occurrence in a separate section of the memory. Then incoming text words could be compared with this small dictionary before comparison with the large memory. This auxiliary small dictionary would be used if the other machine operations take substantially less time than the dictionary search, since its use would undoubtedly speed up the average location time of words. If the dictionary search was fast enough so that the other machine operations were the limiting factors, then the logical complications of two single word dictionaries would not justify splitting the dictionary.

Idioms could be stored in a separate dictionary and incoming words compared with this dictionary before comparisons with the single-entry dictionary. These idioms might also be stored in the same dictionary as the single-word entries. Storing both the idioms and single-word entries in the same dictionary would probably give a lower average location time, but the logical problems would be more complex. The operation of a separate idiomatic dictionary will not be discussed in detail since source language text material could be correlated with this dictionary in the same manner as with the individual-word dictionary although the routine would be somewhat more complicated. This idiomatic dictionary should be small compared with the individual word dictionary.

To store 40 megabits of information on a photographic place in the manner shown in Fig. 1, a square of information about 6,500 bits on a side is required, which yields a total storage of about 4.25×10^7 bits. With 6,500 rows in the large dictionary, the average number of rows passed by the spot before it gets to the proper section is about 3,250. Since the rows also have about 6,500 bits stored in them, the average number of bits read in the proper row would be about 3,250, or a total of about 6,500 bit positions to read, on the average, before a word is located in the large dictionary. If a repetition rate of 100 kc is assumed (this will allow relatively simple transistor circuitry to be used) the average location time for an incoming text word would be about 0.065 second. Thus it seems possible to construct an optical store which would have the required capacity and allow an access time of less than 1/10 second, which was previously estimated as an economical speed of operation.

LOGICAL OPERATIONS

Word-for-word translation has proved surprisingly good, but not satisfactory for commercial translation. Some consideration of the context of words seems necessary to obtain a satisfactory output. Yngve[14] suggests consideration of perhaps three or four words on each side of a particular word when attempting to determine a unique meaning from a set of multiple meanings of the word. He does not suggest the consideration of words not located in the same sentence as the word being processed. To aid in such logical operations, linguistic "tags,"[13] or code sequences which denote certain grammatical information about the word, may be stored in the memory along with the target language equivalents of the word. Every source language word having more than one target language equivalents would require the tag. At present, it is not possible to estimate how much processing would be required, and how much information and of what type should be stored in these tags since linguistic research has not progressed very far in this direction. Some work has been accomplished[13] on grammatical incident meaning but nothing has been done on the nongrammatical incident meaning of words. The logical operations are probably the most important area for contemporary research. To illustrate how the linguistic tags might be used to eliminate impossible target-language equivalents, the following example given by Reifler (page 152 of reference 13) is reproduced. Consider the German expression "wegen dieser Schueler" (because of these pupils). "Dieser" has in isolation the possible grammatical meanings of singular masculine nominative, singular feminine genitive or dative, or plural genitive. The word "Schueler" has in isolation the grammatical meanings of singular masculine nominative, dative, or accusative, or plural nominative, genitive or accusative. Consider the following tag assignments.

1. Singular masculine nominative.
2. Singular feminine genitive.
3. Singular feminine dative.
4. Plural genitive.
5. Singular masculine dative.
6. Singular masculine accusative.
7. Plural nominative.
8. Plural accusative.
9. Singular genitive.

The tags stored with "wegen" will be 4, 9; with "dieser," 1, 2, 3, 4; and with "Schueler," 1, 4, 5, 6, 7, 8. The cooccurrence of "wegen," "dieser," and "Schueler" narrows down the two alternatives of "wegen," the four alternatives of "dieser," and the six alternatives of "Schueler" to only one possibility, that plural genitive since only tag 4 is common to all three.

DECODING

In the decoding operation, material in machine code would be translated in some way into the target-language alphabet. A device has been recently reported which accepts code and translates it into printed form on a cathode-ray screen at the rate of several thousand letters per second.[5] The material can then be photographed, and erased, and new material can be introduced. This printing speed is an order of magnitude greater than the minimum that is required for a translator.

Conclusions

There appear to be no insurmountable engineering problems in the realization of a mechanical translation machine. Research has progressed sufficiently to allow the formulation of a detailed program which should result in a commercially practical machine in a reasonable time. Much work remains to be done, most of which is linguistic in nature, but a substantial number of good engineering problems remain to be solved.

Discussion

M. M. Astrahan (International Business Machines Corporation, San Jose, Calif.): The 42.5-megabit storage unit proposed would be impractical with presently available or contemplated components. As pointed out in reference 12 of the paper, a cathode-ray tube with a resolution of at least 6,500 lines would be required. Also the problems of accuracy and stability in addressing would be prohibitive.

I would think that the use of an indexing system could considerably reduce the amount of sequential scanning required so that memories with smaller sized high-speed sequential access sections, and slower access to each of the sections, could be employed.

Robert E. Wall, Jr.: Mr. Astrahan is perfectly correct in stating that an indexing scheme may be used to allow rapid processing of material with a memory system, as he describes. Such memories are available now, while the memories of the type indicated in this paper are not now actually available. Until very recently, a Clevite-Brush TapeDRUM was considered for dictionary storage and was to be used as follows: Incoming text material was to be stored in a temporary memory in blocks of about 1,000 words, then each word was to be indexed according to its alphabetical order. The dictionary would then have been searched in alphabetical order for the entire 1,000 words at one time. It is possible to obtain a processing time of ten words per second with such a scheme. The disadvantage of this method is that considerable temporary storage space is required to store and index the incoming material; considerably more than would be necessary just for the logical processing alone. It can also be shown that any type of word dissection scheme is rendered very difficult with a dictionary stored on a low random-access memory. Any processing in the source language, such as perhaps would be required for processing the negations of French, is also much more difficult to perform.

Magnetic Amplifier Control of Switching Transistors

H. WILLIAM COLLINS
ASSOCIATE MEMBER AIEE

Synopsis: A series of circuits are presented which use a magnetic amplifier to control the average output power of switching transistors by pulse-width modulation. Thus the advantages of switched-transistor operation are incorporated in a linear amplifier. The magnetic elements serve both as a pulse-width modulator and as a high-gain preamplifier, thereby producing an amplifier with high-gain as well as high-output power. Design considerations, performance data, and potential applications of the circuitry are discussed.

THE ADVANTAGES of operating a transistor in a switching mode have been clearly demonstrated.[1] These advantages can be briefly reviewed by reference to Fig. 1 which shows the characteristics of a power transistor operated in the common emitter connection. When operated in the switching mode the transistor remains either at point *A*, corresponding to high collector current and very-low collector voltage, or at point *B*, corresponding to high collector voltage and very-low collector current. The power dissipation in the transistor at each of these points is much less than the load power which is controlled by the switching action. In contrast, when operating a transistor in class *A* manner, the internal dissipation equals or exceeds the load power. For a given internal dissipation, the power-handling capability of a transistor, therefore, can be increased typically by a factor of 10 by operating in the switched mode. A corresponding increase in efficiency also results. Because the transistor is operated only at saturation or cutoff, nonlinearities of the transistor-control characteristics do not affect operation. Likewise, very stable operation is achieved because normal variations in the transistor parameters, from aging or production inconsistencies, do not affect circuit operation. Stable operation over a wider ambient temperature range is possible. These features have been exploited in a number of recently developed devices[2,3,4] which use the transistor as a switch.

The transistor can provide an excellent high-speed, static switch which has both high output power and reasonably high power gain. The advantages of the switched mode of operation are similarly attractive in constructing a linear power amplifier, but a means of proportional control of the output must be provided. The average output power of a switching transistor can be linearly controlled if the ratio of "on" time to "off" time is varied as shown in Fig. 2. This method of control is termed pulse-width modulation. A group of circuits has been given which operates transistors in the switched mode in power amplifiers.[5] This paper presents a different technique which uses an audio-frequency magnetic amplifier as a means of pulse-width modulating of power transistors. It will be noted that the technique applied in all of these circuits uses a magnetic amplifier not only as a means of pulse-width modulation, but also as a high-gain preamplifier stage. The resultant circuitry is thereby capable of both high power gain and linear control of the output.

Magnetic Amplifier Control

A self-saturating magnetic amplifier is characterized by sharp saturation of the magnetic-core material which transfers the supply voltage from the magnetic core to the amplifier load.[6] By varying the time in the cycle that saturation occurs (i. e., the firing angle), the output power is controlled. An ideal magnetic amplifier has a control characteristic as shown in Fig. 3. The average output voltage varies linearly with the control signal. If a magnetic amplifier is operated from a square-wave a-c supply, the firing angle also varies linearly between 0 and 180 degrees thus producing a variable-width pulse as shown in Fig. 2. The resultant pulse is ideal as a means of linearly controlling the average output of a power-transistor switching stage.

Conventional magnetic amplifiers are operated from power-frequency sinusoidal supplies. The firing angle of such an amplifier varies sinusoidally rather than linearly with control, and thus is not well suited to controlling a transistor stage which operates from a smooth d-c supply. The basic performance of a magnetic

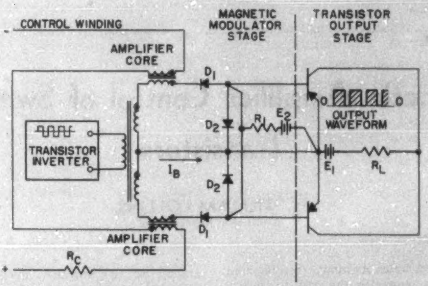

Fig. 5. Basic magnetic-transistor amplifier circuit

amplifier can be greatly increased by operating at high-supply frequencies.[7] Practical high-frequency magnetic amplifiers have been developed[8,9] which have the a-c power supplied by a saturable-core transistor inverter (see Fig. 4). These amplifiers are not only smaller than power-frequency devices, but also have power gains and bandwidths that are normally unattainable in the power-frequency range. Of particular importance in this discussion is the fact that the transistor inverter is a square-wave a-c supply. Therefore, a high-frequency magnetic amplifier has an output pulse whose width varies linearly with control. The magnetic amplifier thus becomes a practical means of linearly controlling switched transistors.

A basic circuit for magnetic-amplifier control of switching transistors is shown in Fig. 5. The magnetic-amplifier stage is a standard center-tapped type of circuit operating at an audio frequency. The power for the magnetic stage is supplied by a center-tapped winding on the saturable core of a transistor inverter. The magnetic-amplifier load consists of two transistors which are pulse-width modulated and their conduction time is linearly varied from 0 to 100% (per cent) by the amplifier control current. In simplest form, the circuit could operate without rectifiers D_1 and D_2, resistor R_1, and voltage E_2. The transistor base to emitter junction can serve as the self-saturating rectifier D_1 for the magnetic amplifier. On the other hand, the leakage of commercially available power transistors is relatively high, and it appears advisable at the present state of amplifier development to use a separate rectifier to assure high gain, linearity, and stable operation of the magnetic stage. A serious problem arises in driving switching transistors from a magnetic amplifier because the magnetizing current (typically several milliamperes) which flows at minimum output allows the transistors to conduct. The situation is greatly aggravated by the high current gain of power transistors at low values of base drive (see Fig. 1). The transistor stage not only cannot be turned off completely but remains operating in the high dissipation region. At high output powers there is great danger of thermal runaway. This problem can be overcome by using biased rectifiers D_2 which bypass the magnetizing current and maintain a positive bias on the transistor base until the magnetic amplifier fires. Isolated d-c source E_1 can be conveniently supplied by a center-tapped rectifier circuit operating from the saturable-core inverter.

Power Gain

The magnetic amplifier serves a dual function as a pulse-width modulator and as preamplifier. In order to evaluate the over-all circuit performance, it is necessary to determine the gain and response of the magnetic stage. The gain and response of a full-wave magnetic amplifier are related by the figure of merit (M) which, for a given amplifier design, is constant over a wide range of response time.

$$M = \frac{A_p}{T}$$

M = figure of merit
A_p = power grain
T = time for 63% response in seconds

The figure of merit of an audio-frequency magnetic amplifier[8,9] is in the range of 10^6 to 10^7. The response time will range from a minimum value of 1/2 cycle of the supply frequency to a maximum value set by the maximum practical ratio of control turns squared (N_c^2) to control circuit resistance (R_c). For a 10-kc magnetic amplifier the time delay may in practice be varied from 0.05 millisecond to about 50 milliseconds by changing the control-circuit resistance. With a figure of merit of 10^7, these delays yield a range of maximum power gains respectively from about 500 to 500,000. In applications where fast response is not required, very-high power gains can be achieved in the magnetic stage. Where greater speed is required, it can be obtained at the expense of increased control power and lower gain. A given combination of time delay and power gain can be effected in a magnetic amplifier at various values of input impedance by appropriately selecting the number of control turns. Thus, this circuitry has an innate means of efficiently coupling to a wide range of source impedances.

The power gain possible with a switching transistor stage is highest at low values of base drive, and decreases as high values of base drive are required. The full signal-power gain of presently available power transistors, operated in a d-c switching circuit with common emitter connection, is about 100. The overall gain of the circuit of Fig. 5 is approximately the multiple of the magnetic- and the transistor-stage gain. Thus, power gains from about 50,000 to 50 × 10^6 are within the range of the circuitry. The voltage gain can be widely altered by selection of the desired input impedance. The magnetic amplifier is basically a low-impedance device, and input resistances greater than several thousand ohms are normally difficult to obtain. Special techniques have been devised, though, which can provide very high steady-state input impedances.[10] It will be noted that the magnetic amplifier normally provides the major power gain of this circuit, and that the switched transistors function primarily as a power-output stage.

Switching Rate

Usually it is desirable to operate these circuits at a high frequency in order to maximize magnetic-amplifier performance and minimize time delays. The maximum practical switching rate is set by the time required for a switching transistor to pass through the high-dissipation region from saturation to cutoff. As this time becomes a significant portion of a half-cycle of the carrier frequency, the average transistor dissipation rises sharply, and the major advantages of the switched operation are lost.

The switching time of presently available power transistors, when maximum collector current in common emitter connection is handled, is about 15μsec (microseconds). The off transient is somewhat longer than the on transient because of hole storage which occurs during the conduction period. The power dissipation of a transistor during the switching period is as follows:[1]

$$P_T = P_L \frac{fT}{3}$$

P_T = average transient transistor dissipation
P_L = maximum load power
f = pulse repetition rate
T = switching time

When switched to maximum collector current, a transistor which can tolerate 5-watt dissipation with a typical heat sink in a 25-degree-centrigrade (C) ambient has about 1 watt collector dissipation. The dissipation caused by leakage at cutoff is lower, being in the range of 0.2 watt. In addition, a dissipation of about 0.5 watt is caused by the base drive. It appears that the maximum practical pulse-repetition rate is in the range where the transient dissipation approximates the maximum steady-state dissipation of, typically, 1.5 watts. Assuming in this example that P_T = 1.5 watts, P_L = 30 watts, T = 15μsec, equation 2 gives a practical pulse-repetition rate of 10,000 pulses per second. Since in this circuitry two pulses occur per cycle, this value corresponds to magnetic-amplifier operating frequency of 5 kc. In practice, the allowable transient dissipation is, of course, affected by such factors as the required output power, available heat sink, and specified ambient temperature range. With presently available power transistors, however, switching rates in the range from 1 kc to 10 kc seem most advantageous.

The switching time of a power transistor is much less in the common-base than in the common-emitter connection. The power gain is also greatly lowered because the current gain in common-base connection is less than unity. The power-handling capability for a given internal dissipation is also significantly reduced.[1] However, in applications where reduced gain and output power can be tolerated, the switching rates indicated above can be increased by at least a factor of 10, using the common-base connection. Magnetic amplifiers can be successfully operated in the megacycle range, and so the speed of the circuit in power applications is currently limited by the switching time of the transistors.

To yield maximum figure of merit, a high-frequency magnetic amplifier should be designed so that the saturated (air-core) reactance of the magnetic core approaches the value of the load resistance.[7] If this design requirement is met, the magnetic amplifier will not have a sharp output pulse because the air-core inductance limits the rise time when the amplifier fires, even though the magnetic material saturates completely. In order to obtain a rectangular output pulse (short-rise time) the magnetic stage should be designed so that the time constant formed by the ratio of saturated inductance to load resistance (L_s/R_L) is slight compared to the transistor switching time. As a result, the maximum figure of merit cannot be realized if the transistor dissipation is minimized. The net effect is that the theoretical power gains previously indicated for a magnetic amplifier are somewhat reduced in practice. This design compromise allows a very good switching pulse to be delivered to the transistors.

Experimental Example

The circuit of Fig. 5 has been constructed, and uses two Minneapolis Honeywell *H-2* transistors in the output stage. The transistor inverter supplies the magnetic amplifier with 9 volts at 5 kc. Germanium diodes are used for the self-saturating rectifiers, and to provide the base bias. The magnetic-amplifier reactors consist of 650 load turns and 800 control turns wound on 1/2-in. (inch) inside-diameter, ceramic bobbins having 32 wraps of 1/2-mil *4-79* Mo-Permalloy. The inverter also uses *H-2* transistors, but lower power transistors are suitable.

A control characteristic of the amplifier is shown in Fig. 6. With a 50-volt supply, the maximum output power is 47 watts. With only the winding resistance in the control circuit (52 ohms) the amplifier has a total power gain of 15 × 10^6 (72 decibels) and response time of 85 milliseconds. The response time can be decreased to a minimum value of 0.1 millisecond by increasing the control-circuit resistance and suffering a corresponding decrease of power gain. A delay of 1 cycle (0.2 millisecond), a voltage gain of 9, and a power gain of 32,000 (45 decibels) will result with a control-circuit resistance of about 20,000 ohms. By a proper selection of the number of control turns, the input impedance, and

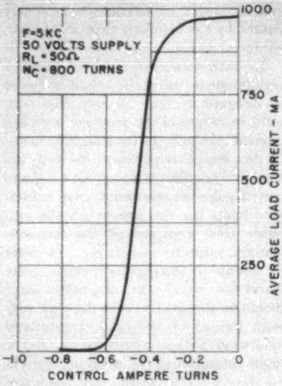

Fig. 6 (left). Control characteristic of magnetic-transistor amplifier

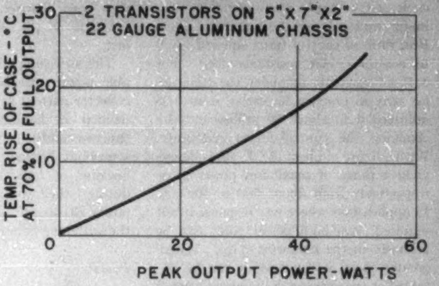

Fig. 8 (right). Transistor temperature rise at pulse repetition rate of 10,000 pulses per second

control-voltage sensitivity, for a given power gain and delay, can be greatly altered.

Fig. 7 shows the output wave form of the inverter and the output wave form of both the magnetic and the transistor stage operating at about 70% conduction with a peak output of 47 watts. This operating point is near the condition of maximum transistor dissipation. The power dissipation per transistor is approximately 5 watts. With the two transistors mounted on a 5-in. by 7-in. by 2-in. 22-gauge, aluminum chassis, and with a mica insulating washer, the temperature rise of the mounting base is 24C. With 5-watt internal dissipation in the *H-2* transistors, a maximum mounting base temperature of 70 C is permissible as has been indicated by the manufacturer. A maximum ambient temperature of 46 C is, therefore, tolerable with this power output. Fig. 8 shows the mounting base temperature rise at 70% conduction for various values of peak output power. It will be noted that the temperature rise is disproportionately high at high output power. The increased rate apparently results from the excess dissipation caused by increased leakage at higher junction temperatures, and by increased switching time at high values of collector current.

Circuit Variations

Variations in the basic circuit shown in Fig. 5 are possible. Fig. 9 shows a doubler-type magnetic amplifier used in a transformer-coupled version of the circuitry. Although it requires an additional transformer, this circuit allows the magnetic amplifier to be operated at a more advantageous voltage level. Using a higher supply voltage, the power-handling capability of the germanium diodes is increased, and their forward voltage drop is of less significance. Also the use of a doubler circuit is advantageous because it does not place full supply voltage on the rectifiers. This configuration is preferable where the maximum possible power is required from the magnetic stage. Unlike the circuit of Fig. 5, the transistors operate on alternate half-cycles.

Fig. 10 shows a circuit which amplifies a-c signals. The transistors are biased off when there is no input signal and operated class *B* into a center-tapped output transformer. The magnetic-stage pulse width modulates each transistor for $1\frac{1}{2}$ cycle of the signal frequency. The control windings are connected so that each side is turned on by opposite polarities of the a-c signal. The carrier-frequency pulses can be filtered, and the signal-frequency power is delivered through a transformer to the load. It is apparent that the a-c signal frequency must be considerably less than the carrier frequency, since each 1/2 cycle is formed from many carrier-frequency pulses. The single-ended circuits shown in Fig. 5 and 9 can also amplify a-c signals, if the d-c output is modulated around a quiescent output level and the signal-frequency power capacitively coupled to the load. A carrier-frequency a-c output can be delivered to the load if the output transistors in Fig. 9 are operated on alternate 1/2 cycles into a center-tapped transformer. The center-tapped circuits inherently place double voltage on the transistors, and the output power of these circuits is halved.

In many applications the carrier-frequency pulses in the output are not desirable. The output of these amplifiers can be filtered, and the input wave form thereby recovered and accurately reproduced. If reduced output power can be tolerated, only one transistor need be used in the output stage of most of these configurations. Greater signal sensitivity can be obtained by using either a low-level magnetic amplifier[11] or a transistor stage as a preamplifier.

It is apparent that it is possible to design a similar group of circuits using a

Fig. 7(A). Output of 5-kc inverter

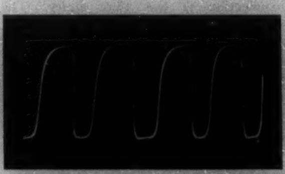

Fig. 7(B). Magnetic amplifier output pulses

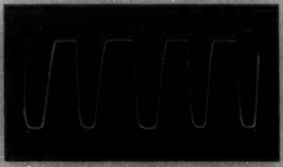

Fig. 7(C). Output of pulse-width-modulated power transistors

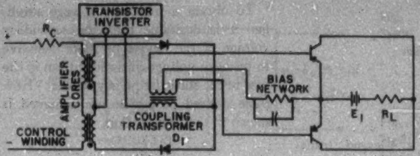

Fig. 9 (above). Transformer-coupled circuit

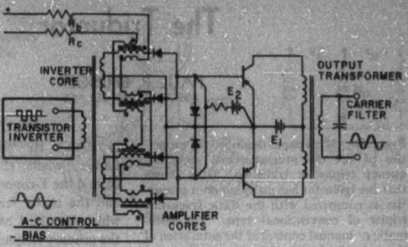

Fig. 10 (right). Switching transistor a-c amplifier

standard power-frequency magnetic stage for control of the transistors. Although the firing angle of a sinusoidally operated magnetic amplifier does not vary linearly with control, the average output can be controlled linearly if the direct current for the switching transistors consists of a rectified, but unfiltered, sine wave. It is believed that the following advantages will justify operation from a high-frequency square-wave source such as proposed in the foregoing, even though additional circuit components are required.

1. The power-handling capability of the transistors is approximately doubled, since they can operate at peak collector voltage throughout the cycle.
2. Much shorter response times are possible, high-gain a-c amplifiers can be built, and much smaller output filters result at the higher operating frequencies.
3. A higher figure of merit is obtained in the magnetic amplifier, and greater power gain is, therefore, possible with a given time delay.
4. The magnetic stage is smaller in size and weight, and is possibly less expensive.
5. The cost of additional inverter components (two low-power transistors and a core) is normally a small part of the total device cost.

Circuit Features and Applications

The circuit techniques proposed in this paper are most advantageous where an efficient linear amplifier of high output power is required. Transistors could be developed which would control many amperes and hundreds of watts of power when operated in the switched mode. As these power levels are realized, the inherent inefficiency and the resultant high internal dissipation make class *A* operation increasingly less practical. Consequently, the advantages of linear control of the average output by pulse-width modulation techniques are increasingly attractive. The amplifier-response time with pulse-width modulation is, of course, longer than with class *A* operation, being a minimum of 1/2 of the carrier frequency (typically 0.05 to 5.0 milliseconds). On the other hand, the relatively slow response is not disadvantageous in most of the probable applications: for example, where time delays from mechanical elements are present.

The linearity of a circuit employing pulse-width modulation is determined primarily by the linearity of the modulating device, and is largely independent of the parameters of the modulated element. A very linear and stable amplifier can be obtained if the gain of the magnetic stage is greatly degenerated by negative feedback. If the switching time of the transistors remains negligible, excellent linearity can be obtained at a high power level by amplification of the modulator output pulses with successive stages of transistors.

These circuits are generally applicable where a high-power high-gain moderate-speed linear amplifier, having the small size, ruggedness, and reliability of magnetic and semiconductor devices, is desired. Such amplifiers are commonly required in servo systems, for example, and in regulated power supplies. Future development of very-high-power transistors should make possible an excellent means of d-c motor-speed control and generator field control.

Conclusions

The power-handling capability and stability of a transistor amplifier can be greatly increased by the use of pulse-width modulation for proportionately varying the average output power. A high-frequency magnetic amplifier operating from a square-wave source provides an excellent means of pulse-width modulating of power transistors. The magnetic amplifier functions both as a stable pulse-width modulator and as a high-gain preamplifier. In addition, the magnetic stage is small and rugged, has speed commensurate with the maximum practical transistor-switching rates, and provides a means of matching input impedance to a wide range of control sources. The basic technique, which combines the high linearity of a magnetic stage with the high power-handling capability of switching transistors, can be applied to various circuit configurations. The resultant amplifiers feature small size, ruggedness, high gain, high power, moderate speed, and linear control of the average output.

The Triductor

PAUL P. BIRINGER
ASSOCIATE MEMBER AIEE

Synopsis: This paper describes the properties of the d-c premagnetized static-frequency tripler or triductor. It is shown that the triductor has many superior properties as compared with the static frequency tripler of conventional type. The automatic or manual control of the saturation of the individual iron cores by superimposed d-c magnetization makes a number of applications practical. Of particular interest are the uses of the triductor as a static frequency transformer with regulated output voltage and its application as a highly voltage-sensitive amplifier.

STATIC frequency changers, as such, have long been known. They came into early use in the field of radiotelegraphy. However unlike most other electric devices, they have not undergone any continuous development during the last few decades. The improvement of magnetic materials with low losses at high flux densities has facilitated the development of static frequency changers during recent years. Only the static frequency tripler and the d-c premagnetized static frequency tripler or triductor are considered in this paper.

Triductors for frequency changing purposes have been used for a few years in the U.S. and Canada. The installations consist of units having 50-kw maximum output power. The use of the triductor as a voltage-sensitive amplifier has been investigated at the University of Toronto and shows considerable promise.[1]

Properties of Static Frequency Tripler

The important characteristic of the static frequency tripler is that its operation is based on the nonlinearity of the **B-H** characteristic. The simplest connection is shown in Fig. 1. Assuming that the terminal voltage ($\mathcal{E}_1$) is so high that the transformer operates above the kneepoint of the **B-H** characteristic of the iron core, then terminal voltage, flux, and the secondary voltage will be distorted. Due to the symmetry of the **B-H** characteristic only odd harmonic components are obtained across the secondary terminals. Any of these harmonics may be filtered out and utilized on the secondary side of the transformer.

Another connection specially for frequency tripling was described by Spinelli in 1912.[2] He used a 4-legged transformer, where the three outside legs carried the *Y*-connected primary windings and the center leg a single winding, in which the third harmonic component of the primary frequency could be obtained; see Fig. 2.

The same result can be achieved by using three identical single-phase transformers with star-connected primary windings and series-connected secondaries, as shown in Fig. 3. The latter is the conventional static frequency tripler.[2-4] This connection has the following properties:

1. The magnitude of the secondary voltage is highly dependent on the value of the primary voltage. This property is not desirable if one wants to use the device as a frequency transformer.
2. The primary power factor is very low, because of the high magnetizing current required at the high flux densities.
3. The reactance behind the third harmonic secondary emf (electromotive force) is relatively high and it limits the high-frequency output power to a small value compared with the size of the transformer.
4. For 29-gauge silicon iron core and a pure resistive load, the transformer efficiency is relatively low, 70 to 80% (per cent), due to the high losses in the iron and in the primary windings.
5. The primary current is distorted. It contains a large percentage of fifth-harmonic component, and for this reason the primary power factor cannot be corrected by capacitors across the primary terminals.

To obtain practical frequency transformation, it is desired that the secondary voltage can be kept constant, independent of the primary voltage variations, that the primary power factor can be corrected, and that the dimensions of the transformer compare favorably with power transformers of the same output power.

To obtain a high gain voltage amplifier it is desirable that the secondary voltage of the device be more sensitive to primary voltage variations than is the case in the static frequency tripler. How these desired properties are achieved is shown in the next section.

Connection and Properties of Triductor

Fig. 4 shows the connection of the triductor designed for operation as a frequency transformer. The diagram shows two core elements in each a-c phase. They are provided with separate primary N_p, secondary N_s, d-c $N_{d\text{-}c}$, and compensating N_c windings. The general properties of this connection are described in the following:

1. The d-c premagnetization shifts the position of the flux wave on the flux axis. The amplitude of the induced third-harmonic emf depends on both the magnitude and position of the a-c flux wave. Consequently, the secondary voltage and power output of the triductor can be influenced by changes in either the d-c magnetization or in the primary voltage. The change in the secondary voltage due to primary voltage variations may be counteracted by a corresponding change of the d-c premagnetizing current. In this way the secondary voltage can be kept constant.
2. With the help of series C_2 or parallel C_3 condensers the high secondary impedance can be counteracted. The possible output power for the same core size will increase. This increase very often corresponds to two or three times the original output power without reaching the region of ferroresonance.
3. Because of the condensers the frequency-transformed power will increase, while the losses will increase only very slightly, therefore the efficiency will have a much higher value than before (90 to 97%).
4. The power-factor-correcting condensers C_1 are placed across a separate winding N_c where the induced emf is already distorted. This connection makes a correction to nearly unity power factor possible. Placing the condensers on the primary side would result in a correction of the fundamental frequency component of the magnetizing current only. At the high operating flux densities it was found that the fifth harmonic current component can reach 50% to 60% of the fundamental. Thus the connection shown in Fig. 4 was used with very good results.

The connection shown in Fig. 4 possesses some unique properties which are advantageous if the triductor is to be used as an amplifier. These properties are as follows:

1. If the primary voltage is kept constant and increasing d-c magnetization is applied to the triductor, the secondary emf dis-

Paul P. Biringer is with the University of Toronto, Toronto, Ont., Canada.

The research reported was supervised by Profs. G. F. Tracy and J. M. Ham, of the University of Toronto, and it was made possible through support extended to the Department of Electrical Engineering, University of Toronto, by the Defence Research Board of Canada, under grant no. *4001–02*, *Project 048-40-01-02*.

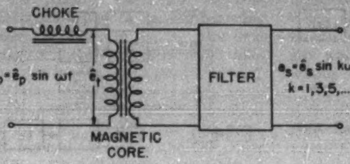

Fig. 1 (left). Static frequency multiplier

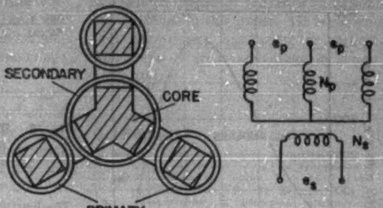

Fig. 2 (right). Static frequency tripler by Spinelli

appears at some definite d-c value. The transfer characteristic is shown in Fig. 5.

2. The triductor will be much more sensitive to primary voltage variations in some regions, than the static frequency tripler. Hence there will be a high gain relating the primary voltage variations to the secondary voltage variations or power output; see Fig. 6. External feedback can be applied to increase this gain.

3. The time delay (primary to secondary) can be reduced without significant changes in the gain. However, one must accept a somewhat lower efficiency.

4. For transients the device has a lead-network character.

These properties are of definite advantage if the triductor is used in a closed-loop regulating system.

Calculation of Triductor Characteristics

The basic equation of the static frequency tripler may be deduced from Kirchhoff's law and from the magnetomotive force law. It yields, for instantaneous values

$$\sum_{k=1}^{3} Hg(b_k+\beta)=\frac{3N_s i_s}{l} \tag{1}$$

where

H=resultant magnetizing force, instantaneous value
b=flux density of fundamental frequency, instantaneous value
β=high frequency flux density, instantaneous value
N_s=number of secondary turns
i_s=secondary current, instantaneous value
l=length of the mean magnetic path
k=number of the primary phases
g=function

The solution of equation 1 is obtained in the two special cases of open-circuited ($i_s=0$) and short-circuited secondary ($\beta=0$) by a trial-and-error method. For instance, in the case of open-circuited secondary the flux densities b_1, b_2, and b_3 are calculated for various time t_1, t_2, . . ., etc. It is known that the third, ninth, etc., components of the flux density are equal in each phase at every instant. Thus one must add the same but unknown flux density β to b_1, b_2, and b_3 so as to satisfy equation 1. Equation 1 is satisfied if the sum of the resultant magnetizing forces H is zero. Because the value of the resultant magnetizing force H is dependent the unknown sums $b_1\pm\beta$, $b_2\mp\beta$ and $b_3\pm\beta$, the result cannot be obtained directly. The use of a nonlinear nomogram can facilitate the solution.

The secondary voltage and current of the loaded static frequency tripler are calculated by solving the difference equation of the secondary side. The following equation is written if a load containing resistive R, capacitive C, and inductive L components in parallel is assumed

$$\sum_{k=1}^{3} M(\varphi_k+\phi)=-9N_s^2\times$$

$$\left[C\frac{\Delta^2\phi}{\Delta t^2}+\frac{1}{R}\,\frac{\Delta\phi}{\Delta t}+\frac{1}{L}\,\phi\right]10^{-8} \tag{2}$$

where

M=resultant magnetomotive force
φ=flux of the fundamental frequency
ϕ=high frequency flux

Equation 1 can be used with some modification for the determination of the secondary open-circuit voltage and the secondary short-circuit current of the triductor.

For any given value of the line-to-line voltage the fundamental components of the flux and of the flux density b across the two elements A and B of the triductor may be calculated. Similarly the flux and flux density (B_s) due to the d-c magnetizing current I can be obtained with the help of the **B-H** characteristic of elements A and B. These two elements are magnetized in opposite directions with direct current, and hence the sum of the flux densities due to I is zero in the two elements

$$B_{sA}-B_{sB}=0 \tag{3}$$

The value of a-c magnetizing force is equal in both elements A and B, at every instant, because the same current is flowing through the elements.

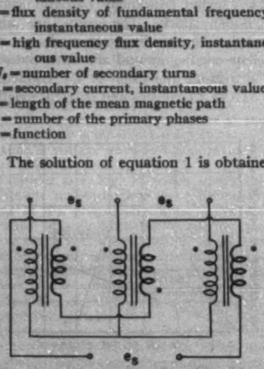

Fig. 3. Static frequency tripler

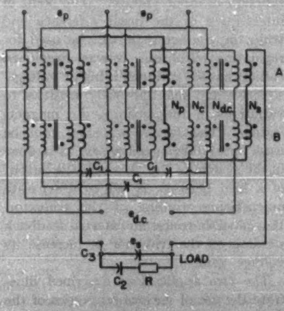

Fig. 4. The triductor with compensating condensers on primary C_1 and on secondary C_2 and C_3 side

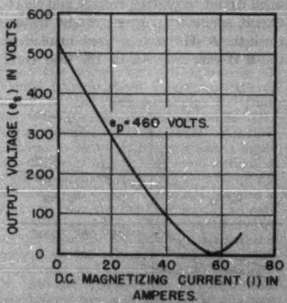

Fig. 5. Transfer characteristic of triductor. Secondary voltage versus d-c magnetization at constant primary supply voltage

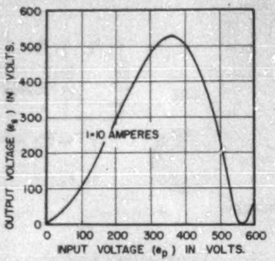

Fig. 6. Transfer characteristic of triductor. Secondary voltage versus primary supply voltage at constant d-c magnetization

$$h_{kA}=h_{kB}=h_k^* \tag{4}$$

The flux density at fundamental frequency (b_{kA}) in element A and the flux density (b_{kB}) in element B change from instant to instant so as to satisfy equation 4 and equation 5

$$b_{kA}+b_{kB}=b_k^* \tag{5}$$

Thus the value of a-c magnetizing force h_k^* can be found for any given line-to-line voltage and d-c magnetizing current I with the help of a $B'-H'$ characteristic, which is obtained in the following way

1. Two auxiliary curves for B_0+b_{1A} and $-B_0+b_{1B}$ are constructed, the former by shifting the original curve horizontally to the left a distance H_0 and the other by shifting the original curve to the right a distance H_0.
2. Curve $B'-H'$ is drawn, the ordinates of which are obtained by adding the corresponding ordinates of the curves B_0+b_{1A} and $-B_0+b_{1B}$; see Fig. 7.

Equation 1, of the static frequency tripler, can be used now to obtain the open-circuit secondary voltage and short-circuit secondary current of the triductor if the **B′-H′** curve is used instead of the **B-H** characteristic of the iron core.

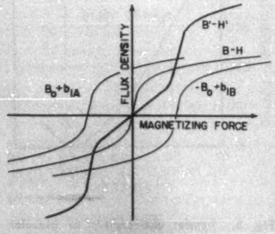

Fig. 7. The $B'-H'$ characteristic of two series-connected triductor elements

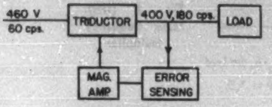

Fig. 8. Block diagram of triductor with regulated output voltage

The load voltage and load current are obtained by solving the difference equation 2 of the secondary side.

Applications of Triductor

Two applications are described here, the first being the use of the triductor as a frequency changer with regulated output voltage. The block diagram in Fig. 8 is related to an installation where several 50-kw triductors are used for induction heating purposes. The net d-c magnetizing current of the triductor is influenced by the deviation of the output voltage from the desired value. When the load conditions or the primary voltage changes, an error voltage is fed back to the triductor so as to restore the original output voltage. Provision is made for manual setting of the desired output voltage or output power. This power triductor has compensating capacitors on the primary side and parallel capacitors on the secondary side. The efficiency at full output, 50 kw, is 92%.

Another application is shown in Fig. 9, where the triductor is used as a voltage-sensitive amplifier in a voltage regulator for synchronous generators.[1] Fig. 10 shows how the output of the triductor is related to the 3-phase input voltage, when the d-c separate magnetization is constant. The same figure gives the output current of a linear element as a function of input voltage. The point of intersection of the linear reference and triductor characteristic can be used for regulating purposes. It was mentioned earlier that the triductor is highly voltage-sensitive and simultaneously sensitive to variations in the separate d-c magnetization. The latter property can be used for stabilizing purposes, as is done in the system of Fig. 9, where the output of a lead network is fed to a separate magnetizing winding of the triductor. It is possible to use an external feedback winding on the triductor to increase its voltage gain.

The two applications described illustrate the use of various properties of the triductor. There are other fields where, again, other properties are of advantage. For instance, in arc furnaces the high frequency helps to obtain a stable arc and the secondary load is symmetrically distributed on the primary side, whereas in practically all other methods the furnace constitutes a single-phase load.

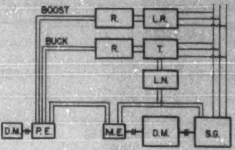

Fig. 9. Block diagram of voltage regulator for synchronous generators employing triductor. R=rectifier, LR=linear reference, T=triductor, LN=lead network, DM=driving motor, PE=pilot exciter, ME=main exciter, SG=synchronous generator

Design and Performance Data

Generally the design of d-c premagnetized frequency triplers is such that the iron cores are not saturated by the applied a-c voltage. The saturation and the generation of third harmonics is achieved by the superimposed d-c magnetization. This method has the disadvantage that only part of the core is participating in the a-c flux reversals. Without the application of any direct current the cores of the triductor are already saturated during a part of the cycle. The result of this design is a better utilization of the cores, which has a great importance in large units.

The core material of the 50-kw triductors is high-quality silicon steel. Each of the six units are made out of standard *E-I* laminations: *VEI* 250 ×4$^1/_2$ inches (Allegheny Ludlum) using a 6-inch stack. The cores are air-cooled. The windings are made out of hollow conductors and are water-cooled. The over-all dimension of the triductor is 32×15×12 inches and its total weight

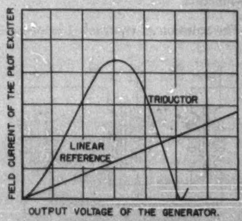

Fig. 10. Operating characteristics of regulator

Vol. 7
Pt. 1
1956

is 620 pounds. There are six condensers connected to the compensating winding, as shown in Fig. 4. The total rating of these condensers is 90 kilovars at 460 volts, 60 cycles per second. The rating of the condensers which are in parallel with the load is 225 kilovars at 180 cycles per second. This high value was required because of the low power factor of the load which is an induction heating coil. In the case of resistive load the secondary condenser requirement is about 30 to 45 kilovars.

The triductor described is able to hold the secondary voltage constant within ±5% if the primary voltage variation is less than ±15%. The power factor of the load must not be lagging at any point of the operation. The required d-c control power is 650 watts, which is not included in the calculation of the efficiency at full power output. There are several 50-kw triductors of similar design which have been in continuous operation since 1953.

The requirements on the voltage-sensitive triductor are such that the use of special core materials is necessary. Mumetal *UBF* stampings have been used in the experimental unit[1] and the dimensions of each element were $2^4/_8$ by $1^1/_8$ by 1 inch. The maximum output power was 18 watts. The response time was less than one cycle of the 60 cycle-per-second supply.

Summary

The properties, basic equations, and practical applications of the d-c premagnetized frequency tripler or triductor are described in this paper. It is shown that this device has many properties which are of great advantage in some applications.

◆

Discussion

N. L. Kusters and **W. J. M. Moore** (National Research Council, Ottawa, Ont., Canada): By the addition of d-c premagnetization to the saturating transformer type of magnetic frequency tripler, Dr. Biringer has produced an effective means of controlling the third harmonic output of this type of device. The circuit makes use of two transformers in series in each phase, thus permitting a d-c magnetomotive force to be applied in opposite polarity to each of the two cores in each phase, as well as prohibiting the generation of any fundamental or third harmonic voltage in the d-c circuit. The composite magnetization curve for each phase produced by this type of connection has certain characteristics which are pertinent to this application and it is of interest to consider how these affect the third harmonic voltages induced in the secondary circuit. For the purpose of this discussion all harmonics greater than the third are neglected.

Fig. 11 shows an idealized magnetization curve for the condition of zero d-c premagnetization. If the secondary is open-circuited, a sinusoidal magnetomotive force of fundamental frequency only will exist in each phase and it will be noted that this produces a square-shaped flux wave in the cores. If this is differentiated with respect to time, a voltage wave with a pronounced third harmonic peak is revealed.

Consider now Fig. 12 which shows the composite magnetization curve for conditions of d-c premagnetization. Note the presence of an additional "break" in the curve which is in the opposite sense to that resulting from magnetic saturation. Applying a sinusoidal magnetomotive force as before, it is seen that this condition yields a peaked flux wave and thence a double-peaked voltage wave.

It is apparent from the two figures that the two types of break in the composite magnetization curve produce third harmonic voltages which are 180 degrees out of phase with each other. This explains the form of the control characteristics shown by the author in Figs. 5 and 6. In connection with these figures, it might be appropriate to mention that the output voltages to either side of the zero output points shown should indicate a phase reversal has occurred.

All this, however, does not explain how power is transferred from the primary at one frequency to the secondary at another frequency, as the previous remarks have dealt with magnetizing currents only, and these in the ideal case convey no power. The author, in his paper, presents a method which relates the input to output wave forms for the case of power transfer. This analysis is valid for any shape of magnetization curve but involves a tedious step-by-step procedure which obscures the process by which energy is transferred. If a more idealized magnetization curve is assumed, it is possible to use the "gating" concept commonly used in magnetic amplifier analysis. This method clarifies the process of energy transfer, at least in a qualitative way. It was used previously by Johnson and Rauch (reference 4 of the paper) in the analysis of a somewhat different third harmonic generator in which the load was connected between the neutral of the supply and the neutral of three saturating reactors. In that case, power was switched into the load by the cores reaching saturation at a certain instant in each half-cycle of voltage in each phase, so that the sequence of pulses received by the load formed a triple frequency current. From the primary viewpoint, however, the power delivered by each phase was at fundamental frequency.

In the circuit proposed by Dr. Biringer, the third harmonic load is coupled in by an equivalent delta connection. The process of energy transfer remains basically the same but the explanation is somewhat different. Before saturation occurs, the total voltage induced in the secondary winding is zero. As soon as one transformer saturates, this voltage is no longer zero but equal to $\sqrt{3}$ times the phase voltage which existed across the saturated transformer before saturation took place.

A few of the points raised in the paper provoke some thought. In particular, it is interesting to read that more effective power factor correction is obtained by means of a separate secondary winding. Possibly this is due to the nonlinear coupling which exists between the primary and secondary, and other windings of this device. Perhaps the author could expand on this point.

The statement that the device exhibits a lead network characteristic is also an interesting one. If the input in this case is considered to be the primary voltage of fundamental frequency, and the output the secondary voltage of harmonic frequency, this point is rather difficult to see and it would be appreciated if some clarification could be provided.

Andrew A. Halacsy (Jeffries Transformer Company, Hollywood, Calif.): This paper is an interesting continuation of Dr. Biringer's work on frequency doublers presented last winter and it may be linked with Conference Paper No. 56-229 presented last winter by W. McMurray of General Electric about frequency triplers, similar to Dr. Biringer's Fig. 3. That one was parallel connected while Dr. Biringer's primary is in series. Another difference is that Dr. Biringer uses a separate d-c winding. I was very interested to see the compensation for power factor by an inductively coupled capacitor because a power factor correction enables the adjustment of the power factor not only by changing the capacitor but also by changing the tapping on the respective winding in the transformer, as I used it some 20 years ago. Dr. Biringer compensates for high load impedances, too, and by this means any load, not only a resistive load, can be used. Could a capacitive load be compensated the same way? The following few points I should like to have clarified.

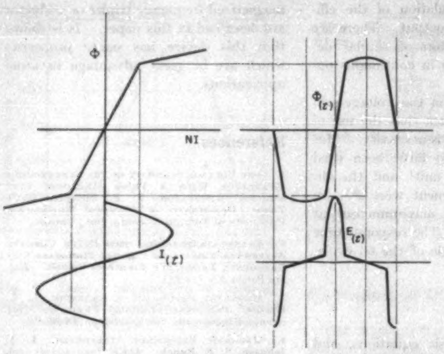

Fig. 11. Idealized magnetization curve for condition of zero d-c premagnetization

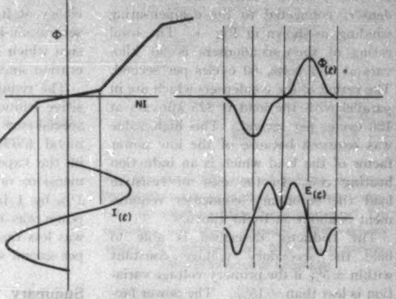

Fig. 12. Composite magnetization curve for conditions of d-c premagnetization

It is mentioned that the triductor will be much more sensitive to primary voltage variations in some regions than the static frequency tripler. Is this not in contradiction with the requirements mentioned in point 1 in the section "Connection and Properties of Triductor?"

Equations 3 and 5 are true if they are transformed into voltage equations. But, as far as flux densities are concerned, one can speak only of imagined flux densities because the resultant flux densities will appear nowhere. Equation 4 is true, of course.

The method of typing is confusing in equations 1 and 2, where a function appears under the sign of summation. Many may assume that the expressions $H(b_k+B)$ and $M(\phi_k+\phi)$ represent products and not a function.

P. P. Biringer: The author wishes to thank the discussers for their interest. The points they have brought out present an opportunity to give the author's views on these matters.

In Mr. Kusters' and Dr. Moore's discussion, the first question concerns the method of analysis. It is quite true that the "gating" concept clarifies the process of energy transfer in a qualitative way. The trouble is that the results of this type of analysis are based on an ideal **B-H** characteristic and if the **B-H** characteristic deviates from the assumed ideal one the results are useless for quantitative calculations. The author's intention is to present a method which can be used for design of triductors. It is appreciated that the step-by-step procedure for calculating the load current of the triductor is tedious, but the method is easily adapted for digital computers. In many cases, it is sufficient to know the no-load secondary voltage and the short-circuit secondary current of the triductor. In such cases equation 1 of the paper is simplified, and it is easily transformed to a nomogram which gives directly the high-frequency flux density or the high-frequency magnetizing force. Fig. 13 shows a nomogram for obtaining the high-frequency flux density, point by point. A further simplification results if it is assumed that the third harmonic component is dominant on the secondary side. In this case the maximum value of the high-frequency flux density and the maximum value of the secondary no-load voltage is obtained in a single reading on the nomogram.

The second question is in regard to the method of power factor correction. The necessity for a separate compensating winding may be illustrated as follows: Under normal operating conditions each core will be saturated during a part of the cycle. This results in a large and distorted magnetizing current, which causes a low power factor under load conditions also. The distortion of the magnetizing current is due not to the third harmonic current components, but rather to the fifth and higher harmonics. From this it follows that the power factor correcting condensers must be placed in such a way that they deliver current of fundamental, fifth harmonic and higher harmonic frequencies. It is important that the voltage across the condensers does not contain any third harmonic component. This is necessary to prevent the dissipation of the third harmonic power into this separate circuit. These requirements are met by using a separate compensating winding as shown in Fig. 4.

The third question brings out a very good point and it is difficult to give a short answer to this question. The transfer equation of the triductor for a sudden change in supply voltage was developed in reference 1. This theory and the actual measurements seem to justify the statement in the paper regarding the lead network properties. It is felt that the deduction of the relevant equations is too lengthy to be given here.

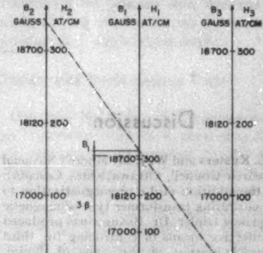

Fig. 13. Nomogram to obtain the high-frequency magnetizing force (β) of a static frequency tripler

Dr. Halacsy questions the possibility of compensating a capacitive load. It should be understood that condensers C_1 in Fig. 4 are compensating only the magnetizing current. Condensers C_2 and C_3 in the same figure are the ones which are used for compensating the reactance of the transformer and the inductive load. Naturally, if the load is capacitive condensers C_2 and C_3 can be reduced in size or entirely omitted. There is a limit to the capacitive load, namely, the point where resonance conditions will arise.

The sensitivity of the secondary voltage of the triductor to primary voltage variations is not of disadvantage because the secondary voltage can still be regulated by the d-c magnetization. This does not apply for the static frequency tripler; the secondary voltage follows the variations of the primary voltage and there is no way to prevent this. It is recognized, however, that for some applications, it would be better to have a constant secondary voltage which is not dependent on the primary voltage variations.

Dr. Halacsy is right that equations 3 and 5 represent imaginary flux densities and I am grateful for his suggestions.

Magnetic Logic Circuit Control System Design Considerations

R. I. VAN NICE
ASSOCIATE MEMBER AIEE

Synopsis: The design of switching circuits for industrial control has been developed chiefly in terms of relays. Magnetic logic circuits, which are switching elements based on the single-core magnetic amplifier, have properties different from relays and therefore require somewhat different design methods. One possible form of switching algebra for magnetic logic circuits is suggested and simple examples of its use are given. The steps in designing a complete system are discussed. The advantages of performing the important step of design verification on a simulator are pointed out.

THE SUBJECT of this paper is the design of switching control systems using as basic components a compatible set of magnetic logic circuits.[1] To clarify the meaning of the terms just used for those who may be unfamiliar with this subject, some background information and references[2] will first be given.

At one time, the term "switching circuit" was applied exclusively to a circuit containing moving-contact switches, such as manual or limit switches, relays, commutators, and stepping switches. With the development of vacuum-tube circuitry, particularly multivibrators, and of gas tubes such as thyratrons, it became evident that devices not containing moving contacts could perform switching functions. The basic characteristic of a simple switch is that it is either open or closed, so that its resistance to current flow is either high or low; the voltage across its contacts or the current through them is either essentially zero or not zero. It is this two-valued, or binary, nature of the quantities observed which is now used as the defining characteristic of a switching element. The list of switching elements now includes vacuum tubes and gas tubes, transistors, square-loop magnetic cores and ferroelectric capacitors, and others.

On analysis, it can be seen that the primary function of switching circuits is to perform logical operations. The variables of elementary logic are two-valued, namely, "true" and "false"; therefore they may be represented by one of the parameters of a switching circuit. The various connections of switching elements then yield the elementary logical functions of these variables such as AND, OR and NOT; and the mathematics of switching circuits is the algebra of logic, or Boolean algebra.[3,4]

Industrial control systems employing switching circuitry could be called logical computers. Input data are derived from push buttons, limit switches, friction switches, etc.; the logical computer takes the input data and computes the output data; and the output data operate solenoids, contactors, etc., which actuate the controlled equipment. Consider as an example an automatic elevator system with inputs from push buttons in the corridors, limit switches at the top and bottom of the shaft, and in the doors and gates, etc. From the state of these switches, the elevator control system must compute which direction the car is to go, at what floor it is to stop, when the door should open, etc.

Numerical computation can also be performed by switching circuits, since arithmetic operations are reducible to the more fundamental logical operations.[5] The history of digital computers shows that the first switching elements used were relays, which were then succeeded by vacuum tubes as higher speeds were demanded. Most recently, transistors and magnetic cores[6,7] have received much attention because they promise high reliability as well as high speed. The switching elements in logical computers have, on the other hand, undergone no change in kind until recently; relays are fast enough for most industrial control applications. The improvement of reliability is, however, of great importance, and for this reason transistor or magnetic core circuits are being proposed to replace relays.

A magnetic logic circuit is not an analogue of a relay, but is instead a device which performs a logical operation on a number of input variables. Thus, a relay network can be replaced by an interconnection of logic circuits which are logically equivalent; but the two networks may be quite different in appearance.[8]

The analysis or synthesis of switching circuits is usually carried out in terms of some form of Boolean algebra. Various modifications have been proposed for special purposes, and termed switching algebra,[2] computer algebra,[9] etc. It will be assumed here that the reader is familiar with the rudiments of Boolean algebra.

Mathematical Description of Magnetic Logic Circuits

The magnetic logic circuits discussed here are essentially magnetic amplifiers used as on-off elements. They are based on the single-core flux-reset amplifier described by Ramey and suggested by him as a computer element.[10] Some of the possible forms taken by these circuits are described in the literature;[1] it is not, however, necessary to have complete knowledge of their physical characteristics in order to design switching circuits. This section presents a mathematical description of the pertinent characteristics of the logic circuits, i.e., their logical, delay, and compatibility properties.

PHYSICAL, LOGICAL, AND DELAY PROPERTIES

A variety of names is given to the two values of the variables of logic and switching circuits. These include: True and False, Yes and No, Active and Inactive, On and Off, and 1 and 0. The last two sets will be used interchangeably here.

Physically, the voltage levels in the magnetic logic circuits represent the logical variables in the sense illustrated by Fig. 1. The transfer characteristic of the simple Ramey amplifier is given in Fig. 1(A) in a somewhat idealized form. The high output level is called ON or 1, and the low output is called OFF or 0. (The low output level is slightly negative because of the use of a biased rectifier across the output terminals to provide a path for magnetizing current.[1,10]) Intermediate output levels are not used to represent information and ideally to not occur in a computing system. Due to the choice of a voltage gain greater than unity, it is possible to obtain unambiguous operation; i.e., full output voltage from an element is more than sufficient to drive the next element to full output. Also, due to the nonlinearity of the transfer curve, the output is insensitive to variations in the input in both the 1 and the 0 ranges.

Another way of displaying these facts is

Paper 56-727, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 28, 1956; made available for printing April 30, 1956.

R. I. VAN NICE is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

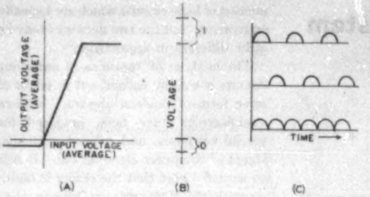

Fig. 1 (left). A—Transfer curve of Ramey amplifier. B—Tolerances. C—Three representations of "1"

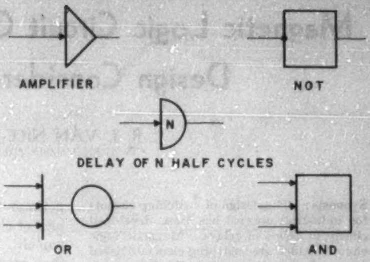
Fig. 2 (right). Block diagram symbols for logic circuits



shown in Fig. 1(B). Any two voltages within a tolerance band about a design center are logically equivalent. These tolerances are valuable because they allow perfectly accurate operation in spite of the unavoidable variations in electrical parameters due to individual differences, aging, environmental conditions, and random fluctuations.

The transfer characteristic of Fig. 1(A) is given in terms of average voltages. On an instantaneous basis, the signals may be either half-wave or full-wave rectified sinusoids, approximately as shown in Fig. 1(C). Due to the half-cycle delay characteristic of the flux-reset amplifier, two phases of signals are used, which are logically equivalent but, of course, not physically equivalent. Similarly, it is possible to build magnetic logic circuits to give full-wave signals (e.g., the flip-flops described by Ramey[10]), and here again 1 and 0 are represented by full and zero output. (Systems in which 1 and 0 are represented by the two phases of signals will not be discussed in this paper.)

The input signals to a logical computer are obtained from switches which are not in general operated in synchronism with the computer power supply. If either rectified alternating current or pure direct current is used to supply the input signals, it is probable then that the first half-cycle of the input signal will be incomplete. As a result, ambiguous signals of value intermediate between 1 and 0 will exist in the system during transients. To secure correct operation, it is essential that the inputs be of more than 2 cycles in length so that at least one correct output may be obtained from the logic circuits fed by the inputs. It is necessary in uncertain cases to study the action of a system carefully to verify its correct operation when the inputs are asynchronously switched. Note that if magnetic logic circuits are to replace relays successfully, the time for 2 cycles must be comparable to the operate time for a relay.

Most numerical computers using magnetic logic circuits would use signals one cycle in length and synchronized with the power supply (clock). Extra equipment is required to convert input signals to this form, but the increase in speed may counterbalance the extra cost. Another factor is that numerical computers tend to have fewer inputs than the logical computers.

We turn now to the question of selecting a suitable mathematical symbolism for magnetic logic circuits from the variety of symbols which have appeared in the literature. (Neither the symbolism nor the algebra that follows is claimed to be novel.) The three significant aspects of a signal in such a system are magnitude, phase, and delay. The magnitude will be represented by a letter such as $A, B, C \ldots$ for inputs, and X, Y, Z for outputs; each of these is to be considered a binary variable which may take on only the values 0 and 1. Where it is desired to indicate phase, the subscripts a and b will be used. The operator D will be used to represent a 1/2 cycle delay in its operand; D^n represents n half-cycles of delay.

The simple Ramey amplifier which has been mentioned briefly introduces a half-cycle delay. If the input is denoted by A and the output by X, then

$$X = DA \tag{1}$$

Equation 1 implies a difference of phase between X and A; the two possible kinds of amplifier are more completely described by

$$X_a = DA_b \tag{2}$$

and

$$X_b = DA_a \tag{3}$$

Equation 2 expresses the fact that the amplifier accepts signals only of phase B, and gives an output of phase A (due to the phase of its power supply). The value of X equals the value of A during the preceding half-cycle (0 or 1).

The logical function variously called negation, NOT, inhibition, or complementation can also be performed by a single-core magnetic amplifier. A bar will be used to indicate the NOT function; as $\overline{0}=1$, $\overline{1}=0$. The equations for the two phases of NOT circuits can thus be written as

$$X_a = D\overline{A_b} \tag{4}$$

and

$$X_b = D\overline{A_a} \tag{5}$$

To illustrate the algebra of the symbols introduced so far, consider the cascade connection of two amplifiers described by equations 2 and 3, with $A_a = X_a$

$$X_b = DX_a = D(DA_b) = D^2A_b \tag{6}$$

Similarly, cascaded NOT circuits (using equations 4 and 5) give

$$X_b = D\overline{X_a} = D(\overline{D\overline{A_b}}) = D^2A_b \tag{7}$$

Therefore the result is the same in both cases: the output equals the input, delayed by one full cycle.

The logical function AND (coincidence) can be performed by an amplifying circuit described by Ramey.[10] The output of an AND circuit is one if and only if all the inputs are one. Algebraically, the AND function is equivalent to multiplication, and will be symbolized in the same ways. For a 3-input AND circuit, phases not indicated,

$$X = D(A \times B \times C) \tag{8}$$

Finally, the logical function of disjunction, or inclusive OR, is best performed by a simple semiconductor diode mixing circuit. The output of the OR circuit is zero if and only if all the inputs are zero. The plus sign will be used to indicate OR, but it must be kept in mind that simple addition is not meant. Because of the absence of an amplifier stage, no delay is introduced by an OR circuit. For three inputs equation 9 can be written [redacted]

$$X = A + B + C \tag{9}$$

The delays introduced by magnetic

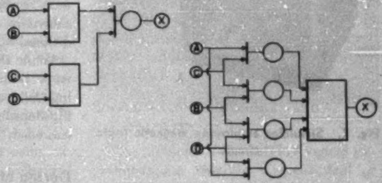

Fig. 6 (right). Logically equivalent circuits

logic circuits are in one sense unavoidable, since they are a result of the mode of operation of magnetic amplifiers. One consequence of these unavoidable delays is that extra amplifiers must occasionally be introduced in a system solely for the purpose of correcting phase or equalizing delays. Another consequence in an industrial control system employing a long chain of logical operations between input and output is that the total delay introduced might be excessive; this situation was not encountered in a study of a number of systems, assuming the use of 60-cycles-per-second magnetic logic circuits.

In many control systems, intentional delays are introduced as safety features, to provide time for an operator action, etc. A relatively short delay may be obtained by cascading several amplifiers, as indicated by equation 6. Longer delays are obtainable from a modification of the single-core amplifier[1]; for example, with a delay core and a buffer amplifier it is possible to construct a device whose equation is

$$X = D^{20}A \qquad (10)$$

i.e., a 10-cycle delay.

It is convenient to have a set of block diagram symbols for the magnetic logic circuits; one proposed set is shown in Fig. 2.

Compatibility Properties

A completely compatible system of logical elements could be interconnected in a completely arbitrary network. No physical elements are capable of arbitrary interconnection, and therefore one must specify the limits on their compatibility. For magnetic logic circuits, these limits include:

1. Phase: Inputs to an element must have the proper phase; correction is always possible by means of inserting an amplifier stage.
2. Delay: Same comment.
3. Loading: The number of inputs which can be fed from the output of a logic circuit is limited. The system designer must know how many inputs of each kind (AND, NOT) can be supplied by the outputs of each type of element. Of course, amplifiers can always be added so as to supply any number of inputs from one source.
4. Voltage drop: The OR element introduces a voltage drop, and therefore the number of OR circuits which can be cascaded is limited. Again, this limitation can be removed by the use of amplifiers.

Thus, if sufficient additional amplifiers are employed, magnetic logic circuits can be made completely compatible.

Storage of Information: Flip-Flops

Storage or memory is a vital function in any switching control system. One of the simplest uses is to store the fact that the START push button for an action has been operated more recently than the STOP push button, or vice versa. Storage is the distinguishing feature of a sequential switching circuit, whose outputs depend on the history of the inputs. Magnetic logic circuits are well suited to store signals since they combine the two properties necessary for regenerative storage: delay and amplification. The term "flip-flop" is applied to a number of bistable storage elements, two of which will now be described. Either of these could be used as a standard-package storage element.

The flip-flop with HOLD input may be built up from simpler logic circuits as shown in Fig. 3(A). Two outputs *X* and *Y* and two external inputs *A* and *H* can be noted in the circuit and, in addition, *Y* is fed back. The analysis of this simple logical feedback system is as follows:

$$X_b = D[(A_a + Y_a)\times H_a] \qquad (11)$$

$$Y_a = DX_b \qquad (12)$$

By substitution

$$X_b = D[(A_a + DX_b)\times H_a] \qquad (13)$$

The meaning of equation 13 can be put into words: "The output *X* is on during a *b*-phase half-cycle if *H* was on during the previous half-cycle and if either *A* was

Fig. 7. Simulator employing magnetic logic circuits

on the previous half-cycle or X was on one cycle ago (or both)." Admittedly, this sentence is awkward, and less useful than equation 13, but both give the essential operation of the circuit. Fig. 3(C) is designed to illustrate the operation more clearly. Starting with $X=0$ and $H=0$, $A=1$ does not turn the flip-flop ON; for $H=1$, $A=1$, the flip-flop does turn ON and stays ON, with the feedback signal Y replacing the momentary signal A; finally, the flip-flop is turned off by momentary loss of H. The input H is called a HOLD input, since its presence is necessary to hold the flip-flop ON. A block diagram symbol is shown on Fig. 3(B).

A typical use for the form of flip-flop just described is in connection with the START and STOP push bottons mentioned earlier [see Fig. 3(D)]. As a safety feature, it is commonly required that the STOP button interrupt a circuit, so that failure of that circuit due to any circumstance will cause the apparatus to stop. Therefore, the STOP button interrupts the HOLD input, while the START button applies the A input.

A second kind of flip-flop[5] is shown in Fig. 4(A). It is in some respects analogous to an Eccles-Jordan circuit. There are two inputs A and B and two outputs X and Y. The equations are

$$X_b=\overline{D(A_a+Y_a)} \qquad (14)$$

$$Y_a=\overline{D(B_b+X_b)} \qquad (15)$$

Combining, and using a familiar result in Boolean algebra

$$X_b=D\bar{A}_a\times\bar{Y}_a=D\{\bar{A}_a\times[D(B_b+X_b)]\} \qquad (16)$$
$$=D\bar{A}_a\times D^2(B_b+X_b)$$

Similarly

$$Y_a=D\bar{B}_b\times D^2(A_a+Y_a) \qquad (17)$$

To translate into words, output X can be turned on by momentary application of signal B and turned off by signal A. Simultaneous application of both A and B turns both outputs off. At all other times, outputs X and Y are complementary; i.e., if one is on, the other is off. Fig. 4(B) gives a block diagram symbol.

The use of this second type of flip-flop with START and STOP push buttons is shown in Fig. 4(B). Note that an additional NOT circuit is required.

While the flip-flops described give half-wave outputs, several methods of securing full-wave output are known. Also, flip-flops having other logical properties can easily be designed.

Design of Logical Computers

The goal of a design method is to provide a straightforward path from problem statement to practical solution. Part of the problem is usually to find either the most economical or the most reliable solution; also, one is restricted by limitations on the compatibility of the logical elements to be used. To one familiar with the difficulties of the design of switching circuits, it is not surprising that no straightforward design method is yet available. There are, however, a number of techniques which are of value to the designer in that they lead him to a number of near-minimal solutions, which can then be examined for economy, reliability, and compatibility.

Since this paper is not intended to be an exhaustive treatise on switching circuit design, the discussion will be confined to general considerations and to problems arising specifically from the use of magnetic logic circuits. References 2 and 11 through 16 may be consulted for further details on design methods. In the practical situation, one may be fortunate enough to be faced with so simple a system that the best solutions can be seen after only a small amount of trial and error. Or one may not be required to find the best solution, but only an adequate solution. At the worst, confronted with a truly complex system, the results obtained will depend on the time available and on ability or experience.

DESIGN BY TRANSLATION

If a switching circuit has already been designed in terms of one kind of switching element, it is a temptation to translate directly to another kind of switching element. This situation has arisen in replacing relay control systems with magnetic logic circuit computers, since contacts in parallel are simply equivalent to an OR circuit, contacts in series to an AND circuit, etc. The pitfalls along this path are several. First, the original system may not have been well designed; as an example, one system encountered had been modified piecemeal several times with the result that seven relays were being used to perform functions for which three relays are sufficient. Second, the original system may have been designed with the inadequacies of the switching elements to be used as a basic limitation; it is therefore possible that improved control functions could be performed by improved switching elements. Third, the compatibility properties of the two kinds of switching elements will probably be different, so that direct translation may lead to wasteful use of elements or to a system which will not operate properly. To avoid these pitfalls, it would seem best to take a fundamental approach to the problem of system design and to use previously designed systems mostly for comparison and checking. These comments apply particularly to the replacement of relays by magnetic logic circuits, and are intended as a warning to relay circuit designers who, because of years of experience, habitually think in terms of relays.

FUNDAMENTAL APPROACH

If one abandons the approach of direct translation, he may then follow steps such as these:

1. **Statement of the problem, including a complete description of the desired input-output relations and of requirements such as economy or reliability.**
2. **Development of near-minimal switching systems satisfying the input-output relations.**
3. **Examination of these possible solutions to determine which one best fits the remaining requirements of the problem statement.**
4. **Verification of the operation of the system by calculation or the use of a simulator.**

Each of these steps will now be discussed further.

INPUT-OUTPUT RELATIONS

The description of a logical computer in terms of what outputs are to result from given input conditions would seem at first glance to present little difficulty. Actually, an intimate familiarity with the apparatus to be controlled is essential. For example, considerable simplification can often result from a knowledge of what combinations or sequences of inputs will never occur.[14] Again, several possible logical patterns for control may exist, as in automatic elevators, and the designer must be able to determine somehow whether one pattern is mandatory or whether several are equally desirable. Finally, the designer must know the requirements of safety codes as they apply to the nature of the inputs which can be used and to provisions for fail-safe operation. Perhaps it would be ideal for this intimate familiarity with the equipment to be combined with expertness in switching circuit design in a single person, the designer. Practically, collaboration between two or more people is usually required, and is actually preferable because it leads naturally to a reanalysis of the control requirements for a system.

The first step in the specification of input-output relations is the definition of symbols for the input and output quantities. An important part of the definition in each case is a clear statement of when the quantity is 1 and when it is 0. For example, the actuation of a STOP push button S interrupts a circuit; is $S=1$ to mean that the button is pushed, or that the circuit is transmitting a signal? Either choice is permissible so long as there is no confusion in the mind of the designer. It is often convenient to define additional intermediate variables to represent those combinations of input variables which occur most frequently.

Switching circuits not involving the storage of information are called combinational circuits. Specification of input-output relations is relatively simple when the number of variables is small; either a table of combinations or a Karnaugh map[15] may be used, for example.

The requirement of information storage in a system makes it a sequential circuit, and complicates its specification. The flow chart introduced by Huffman[14] is probably the most complete method of representing the action of a sequential circuit. Again, the number of input variables which can be handled readily is limited to perhaps five. Other representations of sequential circuit operation are of course possible.[16]

Methods which have been suggested for handling larger numbers of variables include three and higher dimensional representations.[15] More obvious expedients are to split a complex system into parts which can be studied separately, and to identify combinations of variables which can be treated as a single variable. It is unfortunate that the problem statement cannot be generated by a large-scale digital computer.

English language statements are also used to clarify the desired operation of a logical computer; in particular, the operation of a relay control system is often written out in detail to aid in the understanding of the operation of the system. Expressing logical relations in sentences is in some cases very simple since the logical relations AND, OR, and NOT are closely related to the corresponding ordinary words. Ambiguity is possible in the case of OR, since there are two possible meanings of "A or B": first, the inclusive "or," which we have symbolized by OR, translated as "A or B or both"; second, the exclusive "or," which is read "A or B but not both." The other source of difficulty in sentences is that which is solved by the use of parentheses in equations. For example, the statement "X is on if B and C or D is on" could be interpreted either as $X=B\times C+D$ or $X=B\times(C+D)$. More complex statements cause increasing difficulty which can be overcome by defining intermediate variables or introducing parentheses or other punctuation in the sentences. The language techniques used by patent lawyers offer another possible approach which, however, will probably never become popular.

Two rather simple examples of logical expressions will now be given in a variety of representations. Words: "X is on if either B and C are both on or D is on"; "X' is on if either B and C are both on or D is on, but not both." A table of combinations follows:

B	C	D	X	X'
0	0	0	0	0
0	0	1	1	1
0	1	0	0	0
0	1	1	1	1
1	0	0	0	0
1	0	1	1	1
1	1	0	1	1
1	1	1	1	0

Karnaugh maps follow:

X

D \ B,C	00	01	11	10
0	0	0	1	0
1	1	1	1	1

X'

D \ B,C	00	01	11	10
0	0	0	1	0
1	1	1	0	1

Disjunctive normal form follows:

$$X=\bar{B}\bar{C}D+\bar{B}CD+B\bar{C}D+BC\bar{D}+BCD$$

$$X'=\bar{B}\bar{C}D+\bar{B}CD+B\bar{C}D+BC\bar{D}$$

Simplified expressions (readily obtained from the maps or from algebraic manipulation of the preceding expressions) follow:

$$X=B\times C+D$$

$$X'=(\bar{B}+\bar{C})\times D+B\times C\times\bar{D}$$

Finally, block diagrams are shown in Fig. 5. Block diagrams are of value because they can be used directly as schematic diagrams if the set of logical building blocks is sufficiently compatible.

None of these descriptions includes the effects of delays in the logical elements. However, after the equations and/or block diagrams have been derived, it is simple enough to analyze delays and introduce additional delays as needed for compatibility.

SIMPLIFICATION, ECONOMY, AND RELIABILITY

The problem of simplifying logical expressions has received a great deal of attention, and a number of techniques have been described in the literature.[11,12,13] They are based on a systematic application of certain identities in Boolean algebra. While their use is limited to perhaps seven or eight variables when the work is performed by human beings, the use of digital computers may be expected to extend this number and to reduce the time required.

Reducing the occurrences of variables may or may not lead to a reduction in cost. If one element (such as the OR) costs less than another (such as the AND), it may be preferable to increase the number of elements. Thus, the identity

$$AB+CD=(A+C)(A+D)(B+C)(B+D)$$

leads to the two block diagrams of Fig. 6. The form containing three logical elements may prove more expensive than that with five. If relative reliability figures can be assigned to the various elements, similar reasoning is applicable.

VERIFICATION

The most convincing evidence of the correct design of a system is a demonstration of its correct operation. Also, demonstration is perhaps the best method of showing the relay control system designer that his relay actually can be replaced by magnetic logic circuits with no moving parts. The apparatus used for such demonstrations is called a simulator, and consists of a large collection of logical building blocks which can be interconnected to form any switching circuit desired. Input variables can be controlled by toggle switches or push buttons, with pilot lights for indication. Similarly, output indication can be obtained with pilot lights or, for more dramatic demonstrations, the output signals can be used to control operating models of the actual apparatus to be controlled. Fig. 7 shows a typical simulator.

A most important use of the simulator applies to education. There is no simpler or quicker way than the use of the simulator of demonstrating the elementary logical operations, their simple combinations, and logical feedback circuits to personnel unfamiliar with switching circuits. Comparable simulators with relay elements are in use at Massachusetts Institute of Technology and Bell Telephone Laboratories for verification and education.

Verification of system design can also be performed mathematically if the compatibility properties of the logical elements have been well established. Some electronic digital computers which work in the binary number system have in their set of instructions the logical operations AND, OR, and NOT; and the memory can be used to simulate flip-flops. It is therefore possible to program such a computer to calculate the output for every set and sequence of inputs and to print out the results.

Verification of a large system can usually be accomplished by breaking it down into smaller parts. Often, design will have been started by making the same breakdown, and then verification can keep pace with design.

Conclusions

This paper discusses the logical properties of a set of magnetic logic circuits and presents a simple algebraic representation of their performance. The effects of the physical characteristics of magnetic logic circuits on various aspects of switching circuit design are noted. Finally, the advantages of simulators for verification and education are pointed out.

Magnetic logic circuits present the system designer with a number of new and interesting problems. In addition, there remain the standard unsolved problems of switching circuits: how to find the most economical circuit, and how to handle many variables. Ingenuity will continue to be a major tool in design work in the foreseeable future.

A Data Transmission Machine

C. R. DOTY
ASSOCIATE MEMBER AIEE

L. A. TATE
ASSOCIATE MEMBER AIEE

MODERN business operations have developed a requirement for rapid and accurate communications involving the exchange of engineering, scientific, statistical, and accounting data. The terminal points may be in the same building or separated by hundreds of miles. The Armed Forces have the same requirements but the distances may be greater, and radio transmission must be used where wire facilities are not available.

The requirements for a communication system for transmitting data are substantially different from the requirements for transmitting message traffic. The fundamental difference lies in the degree of accuracy required. In message traffic, the inherent redundancy of English text permits reading through an occasional error. By comparison, the inherent redundancy in data is extremely low, and a single error may cause misinterpretation of the message. For this reason, an error-detecting means must be used to obtain accurate data transmission.

A second difference lies in the means for recording the information. Message traffic usually is recorded as printed copy. Data usually are recorded for reading by other data-processing machines, which use either punched cards, magnetic tape, or paper tape.

Equipment designed for message traffic has been applied successfully to some forms of data transmission, by the use of paper tapes to operate automatic telegraph machines. Extensive communications systems of this type have been in operation since 1941, when card-to-tape and tape-to-card translating machines were marketed. However, extra steps of data processing usually are required in preparing and utilizing the paper tapes, and existing telegraph machines do not use error-detecting codes.

This paper describes a new machine, the Data Transceiver, which is designed to meet the requirements for rapid and accurate transmission of all types of data.

Paper 56-985, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1–5, 1956. Manuscript submitted June 14, 1956; made available for printing August 7, 1956.

Description

The IBM (International Business Machines) Data Transceiver reads and transmits information from punched cards, and records the information by punching cards at the receiving location. Transmission may be over telephone or telegraph circuits, using wire, radiotelegraph, or microwave.

As shown in Fig. 1, the machine is composed of two units. The unit on the right contains the card reading and punching mechanisms, the control keyboard, and circuits. The unit on the left contains the electronic commutator and circuitry for transmitting and receiving signals. Different types of signal units are used for telephone and telegraph operation because of the difference in signalling requirements of the two types of circuits.

Telegraph signal units may be operated at any of the standard keying speeds of 60, 75, or 100 words per minute, transmitting three, four, or five cards per minute if all 80 card columns are transmitted. The keying speed is determined by a pluggable speed selector, which may be changed by the operator to match the rated speed of the telegraph circuit.

Telephone signal units transmit and receive tone signals at the rate of 11 cards per minute if all 80 card columns are transmitted. Since this speed does not require the full bandwidth of a telephone circuit, the band is divided into four channels for the simultaneous operation of four pairs of machines. Thus, a single circuit can transmit 44 cards per minute. The channel separation is accomplished by band-pass filters, which are pluggable to permit the operator to change the channel assignment of a machine.

Error Detection and Correction System

The code used in punching cards contains 12 elements per card column, but only 50 alphabetical, numerical, and special characters are in common use. Four additional code combinations are used for signalling, but are not punched into the cards. The card code is translated to use fewer code elements, which permits more efficient use of the information capacity of the transmission line. A minimum of six code elements is required to make these 54 code combinations without using figure and letter shifts.

The error-detecting code is formed by adding two redundant code elements to each character so that each transmitted character contains four marking and four spacing code elements, as shown in Fig. 2. The receiving machine checks each character by counting the marking code elements. A transmission error is indicated if the received code combination is anything other than one of those listed in Fig. 2. Thus, the receiver can detect all single errors and all multiple errors, except those which compensate each other to produce no net change in the number of marking or spacing elements in a character. This error-detecting code was chosen on the basis of field-testing experience, to provide the required degree of accuracy with a minimum of redundancy added to the message. These tests were conducted on many types of communications circuits, including transoceanic radio.

In addition to the fixed-count and invalid-code combination checks of each character, the receiving machine performs other checking functions, including a check to see that the correct number of characters is received for each card, and that the machine is not out of cards. Detection of any failure stops both the transmitting and the receiving machines. The receiving machine stops immediately upon detecting a failure. The transmitter stops at the end of the card being transmitted when the failure occurred. So that the receiving machine can exercise complete control over the transmitting machine, the transmitter is arranged to stop at the end of each card and send a special code combination (end-of-card). If no failure has been detected the receiver responds by sending an acknowledging signal (start). Reception of this acknowledging signal permits the transmitter to feed the next card

and resume transmission. If a failure is detected, and the receiver does not transmit the acknowledging signal, the transmitting machine stops. Both machines then must be restarted by the operators, and the transmission of the card is repeated. In this manner, detectable errors or other failures may be corrected immediately so that each received card is a complete and checked transmission.

SIGNALING CHARACTERISTICS

The 8-element code is transmitted in a 10.5-unit start-stop cycle. A synchronizing pulse, with a duration of one unit, is transmitted first, followed by the eight code elements and a stop interval which is at least 1.5 times the duration of a code element.

Polar relays are used for both transmission and reception of telegraph signals on either full-duplex or half-duplex neutral circuits. A machine may be operated at any of the standard keying speeds of 60, 75, or 100 words per minute (22.75, 28.4, or 37.1 dot-cycles per second). The speed is determined by a pluggable oscillator unit which may be changed by the operator.

Electronic circuitry permits the receiver to use extremely short samples of 50 microseconds for regenerating the received signals. Thus, distortion of the received signals will not interfere with the proper operation of the receiver, unless the distortion is so severe that it affects the center of a signal pulse. On circuits which use regeneration for printer operation, the regenerative repeaters must be disconnected during card transmission because of the different code characteristics.

For operation on telephone circuits, the transmitted signal is an audio-frequency carrier, the amplitude of which is modulated by keying the carrier on and off. When no signals are being transmitted the carrier is off, which permits the receiver to transmit acknowledging signals to the transmitter on the same carrier frequency. Signals are transmitted at the rate of 90 dot-cycles per second in a channel which occupies a bandwidth of 500 cycles per second. As many as four pairs of machines may be operated simultaneously on one telephone circuit, with each pair operating independently of the others on a carrier frequency of either 800, 1,300, 1,800, or 2,300 cycles per second. Band-pass filters are used for both transmission and reception to reduce interference from signals on the other channels.

Operation

TRANSMITTING

Fig. 3 is a block diagram of the Data Transceiver operating as a transmitter. Each card column which is to be transmitted, as determined by the program controls, is read by the electromechanical card reader. Electrical contacts in the reading mechanism operate relays through a diode encoding matrix. Contacts on the relays complete the translation from the card code to the transmittal code.

Operation of the card reader also starts the electronic commutator, which determines the timing of the transmitted signals. The timing reference is obtained from a clock oscillator, with different frequencies used for the different operating speeds. This oscillator starts and operates through ten cycles during the transmission of one character. At the end of this commutator cycle the oscillator is stopped. The first oscillator cycle is used to generate the synchronizing pulse. The next eight cycles determine the time sequence and duration of transmission of the eight code elements. The last oscillator cycle occurs during the stop interval.

The thyratron coincidence circuit compares the timing signals with the output of the encoder. Coincidence of a timing signal and the corresponding code output generates the serialized keying signal, which keys the transmitter. The transmitter is either a polar relay for operation on telegraph circuits, or a pulsed oscillator and band-pass filter for operation on telephone circuits.

RECEIVING

Fig. 4 is a block diagram of the Data Transceiver operating as a receiver. In telegraph operation, the received signals operate a polar relay. For telephone operation, the received signals pass through a band-pass filter, adjustable loss pad, amplifier, detector, and clipping amplifier. The line loss of the telephone circuit is compensated by the adjustment of the loss pad, while normal variations in the line loss are compensated by an automatic regulating circuit in the clipping amplifier.

The synchronizing signal, which precedes the eight code elements in each character, starts a cycle of the electronic commutator. The commutator cycle is not started, however, until the received signal is sustained for a 1/2-unit duration. This delay minimizes the probability that noise will cause false starting of the commutator. A receiving commutator has an operating cycle of ten units, but a transmitting commutator has a minimum cycle of 10.5 units. This time difference permits start-stop operation when the same clock oscillator frequency is used for timing both commutators.

The receiving commutator generates a series of nine sampling pulses, eight of which occur at the mid-point of the correct time of reception of the eight code elements. The coincidence of a received signal and a sampling pulse causes ionization of a thyratron, whose output current operates a coding relay.

The ninth sampling pulse occurs during the stop interval of the receiving commutator. This should occur in the stop interval between successive received characters. If a signal is received at this time, it may indicate that the receiving commutator is not in a proper synchronism with the received signals. Therefore, coincidence of a received signal and this ninth sampling pulse is treated as an error, and the receiving machine is stopped.

Contacts of the coding relays are used in the checking circuits for the detection of erroneous and invalid code combinations. Legitimate code combinations are translated into the card code by other contacts on the coding relays, and the output of the decoding circuit operates the card punching mechanism.

The same electronic commutator, thyratron coincidence circuits, and the coding relays are used for transmitting and receiving. Switching from one condition to the other is performed by relays which are operated by the program controls.

MISCELLANEOUS FUNCTIONS

Means are provided so that the operators may exchange co-ordinating signals

Vol. 7
Pt. 1
1956

to indicate that the receiving machine is ready for operation (start), that communication is desired on an alternate facility (telephone or telegraph), and that transmission is completed (end-of-transmission).

Other machine functions are used to adapt the Data Transceiver to established practices in using punched cards. The machine is controlled by programming the desired machine functions for each card column.

1. Card columns may be skipped, and skipping may be started in the same column of every card or by a control code punched in the card.
2. Information that is to be punched into all cards may be duplicated from one card to the next. Duplicated information is not transmitted.
3. During the time a receiving machine is skipping or duplicating, it cannot accept information from the transmitter. The transmitter may be stopped until the receiver is ready. At this time the receiver transmits a special code combination (restart) which causes the transmitter to resume transmission.
4. The machine normally stops on blank card columns to detect a failure of the card reader. This check may be disabled for any card columns in which blanks are permissible.
5. A machine may be equipped with a printing mechanism, which prints received or duplicated information on the card as the card is punched. Printing may be suppressed in selected card columns.

The operation of the machine is controlled by means of a program card, prepared by punching machine instructions in each column. This card is wrapped around a drum which rotates in step with the card-handling mechanism. Sensing contacts read the instructions and operate relays to control the machine. The transmitting and receiving programs need not be identical, but must be compatible, because the receiving machine will stop if an incorrect number of card columns is received, or if signals are received when the machine is not in the proper program condition.

Summary and Conclusions

The Data Transceiver may be operated on either wire or radio communication circuits. Punched cards are used for both input and output of data, and the machine has the programming flexibility required in using punched cards. The error detection and correction system supervises the operation of both machines. Field-testing and operating experience indicates that an extremely high degree of accuracy is obtained on all types of circuits.

The present uses of Data Transceivers and the increasing interest shown in them by commercial and military planners indicate that Data Transceivers will find a wide field of application in data transmission.

Synchronization Accuracy Obtainable with Multiplier Phototubes

LEO LEVI
ASSOCIATE MEMBER AIEE

Synopsis: The jitter in multiplier phototube synchronization systems is analyzed. The effect of bandwidth, phototube, and optical parameters on jitter is determined, and optimum operating parameters are derived. In the Appendix the intensity range of superiority of the multiplier phototubes over simple vacuum phototubes is determined.

ONE METHOD of obtaining accurate synchronization of rotating components with electronic signals is by the use of multiplier phototubes. Accuracies of the order of a millimicrosecond have been obtained with this method. The synchronization signal is obtained by scanning a light beam, usually a slit image, across a slit located in front of the phototube. The scanning is done by reflecting the light beam from a mirror fastened to the rotating component. A possible arrangement is shown in Fig. 1. [Light from the source is imaged on the source slit by means of the condensing lens L_1 (shown as two plano convex elements). Lens L_2 images the illuminated source slit on the phototube slit, if the rotating reflector is in the proper position. Lens L_3 images the exit pupil of L_2 on the photo cathode. As the reflector rotates, the slit image is scanned across the phototube slit and at the instant of coincident a light flash will strike the photo cathode. The resulting current pulse can be used for synchronization.]

As the object of the arrangement is synchronization, it is of great interest to know the amount of jitter introduced by the noise in the phototube. An attempt is made here to derive an expression for this jitter.

Since both the noise and the pulse rise-time are intimately connected with the bandwidth of the phototube circuit, the bandwidth required for minimum jitter is of interest also.

In the first part of this paper, arbitrarily fixed optical components are assumed and the bandwidth required to yield minimum jitter is determined. In the second part, optical components are taken into consideration as variables and their function in optimizing synchronization is determined.

Electronic Considerations

First an attempt will be made to derive the amount of jitter inherent in the circuit involving the phototube for any given optical rise time and light intensity.

Let the pulse rise time $=\tau$, the jitter $=\Delta t$, and the signal-to-noise ratio $=s$. Then it can be shown that

$$\Delta t=\tau/s \tag{1}$$

This may be derived from Fig. 2, where a pulse with rise time τ is illustrated. If the synchronization pulse is triggered at voltage V_t, it is apparent that the jitter $\Delta t=\overline{ec}$, when the noise $n=\overline{ed}$. Now, triangles *abc* and *ced* are similar and the following can be written

$$s=\frac{V_t}{n}=\frac{\overline{cb}}{\overline{ed}}=\frac{\overline{ab}}{\overline{ec}}=\frac{\tau}{\Delta t}$$

from which equation 1 follows.

Assume, letting Δf equal the bandwidth,

$$s=K/\sqrt{\Delta f} \tag{2}$$

Paper 56-759, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted October 3, 1955; made available for printing May 2, 1956.

Leo Levi is with the Fairchild Controls Corporation, New York, N. Y.

The results reported here were obtained in part under contract with the Evans Signal Corps Laboratory at Belmar, N. J.

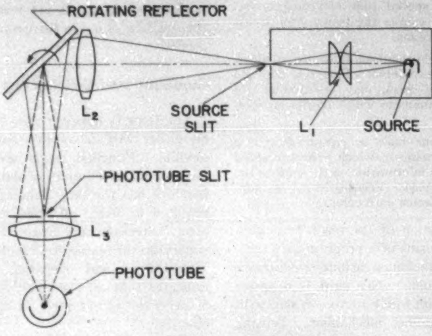

Fig. 1. Synchronization system-optical schematic

where K is signal-to-noise at one cycle-per-second bandwidth. This is based on the assumption of white noise where noise energy is uniformly distributed over the frequency band and therefore noise voltage squared is proportional to bandwidth. This assumption has been verified experimentally and is true for frequencies up to 10^8cycle-per-second.[1] Since $s \propto 1/\text{noise}$, equation 2 follows. Nothing further is assumed concerning noise at this point.

A second assumption will be that the electrical rise time is inversely proportional to bandwidth, i.e.

$$\tau_e = \frac{k}{\Delta f} \tag{3}$$

where k is usually taken to be 0.35.[2]

Assume further that the rise times will combine in the following manner

$$\tau = \sqrt{\tau_0^2 + \tau_e^2} \tag{4}$$

where τ_0 is the optical rise time. This is based on Laplace's "central limit theorem" of probability.[3] Substituting equations 2, 3, and 4 into 1 gives

$$\Delta t = \frac{\sqrt{\Delta f}}{K}\sqrt{\tau_0^2 + \frac{k^2}{\Delta f^2}} = \frac{1}{K}\left(\tau_0^2 \Delta f + \frac{k^2}{\Delta f}\right)^{1/2} \tag{5}$$

Differentiating and equating to zero gives

$$\frac{d\Delta t}{d\Delta f} = \frac{1}{2K}\left(\tau_0^2 \Delta f + \frac{k^2}{\Delta f}\right)^{-1/2}\left(\tau_0^2 - \frac{k^2}{\Delta f^2}\right)$$

$$= 0 = \tau_0^2 - \frac{k^2}{\Delta f^2}$$

and the bandwidth for minimum jitter

$$\Delta f = \frac{k}{\tau_3} = \frac{0.35}{\tau_0} = \frac{0.35}{\tau_e} \tag{6}$$

(the last member from equation 3)

It is seen therefore that $\tau_0 = \tau_e$ and $\tau = \sqrt{2\tau_0}$, and it may be concluded that the minimum jitter resulting will be

$$\Delta t_{\min} = \left(\sqrt{\frac{0.35}{t_0}}/K\right)\sqrt{2}\tau_0$$

$$= \frac{\sqrt{0.7\tau_0}}{K} = 0.837\frac{\sqrt{\tau_0}}{K} \tag{7}$$

Up to this point nothing has been assumed concerning the noise except that it be "white" and on this basis the following conclusions have been arrived at:

1. For minimum jitter the optimum bandwidth is that which makes the electronic rise time equal to the optical rise time.
2. The jitter is then directly proportional to the square root of the optical rise time and inversely proportional to the signal-to-noise ratio at unity bandwidth.

The value of the noise figure K will now be determined. In general, noise in phototubes consists of shot noise due to the "graininess" of the electronic emission, Johnson noise in the load resistor, thermionic emission, and the ohmic leakage current.

In high bandwidth units, light levels are usually low (cf. the narrow slit necessitated by low optical rise time) and for this reason multiplier phototubes are imperative.[4,5] Since at room temperature the Johnson noise is negligible when the voltage drop across the load resistor is much more than 50 millivolts and, as a rule, this condition is met in the case of the multiplier phototubes, Johnson noise will be neglected here.

Similarly, it is assumed that operation will be at light levels considerably in excess of the "equivalent noise input" so that thermionic and leakage currents, too, may be neglected. This leaves only shot noise to be considered.

Shot noise from a single cathode is given by

$$i^2 = 2eI_0\Delta f \tag{8}$$

where i is the noise current, I_0 is the average cathode current, e is the charge of the electron and Δf is the bandwidth of the associated circuitry. This expression holds for $1/\Delta f$ large compared to the electron transition time.

When multiplier phototubes are used, the shot noise from the photo cathode is multiplied along with the original signal, so that the signal-to-noise ratio remains essentially constant. It is somewhat decreased by shot noise in successive dynodes. This reduction factor can be shown to be equal to

$$\sqrt{\frac{m-1}{m-1/M}}$$

where m is the multiplication at one dynode and $M = m^n$ is the total multiplication factor.[5,6]

Another factor decreasing the signal-to-noise ratio is imperfect electron focusing. This produces nonuniform gain over the

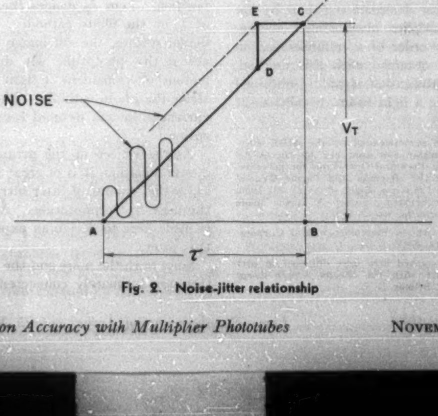

Fig. 2. Noise-jitter relationship

cathode area and consequently multiplies the noise by the rms of M which is more than the mean M. Thus the signal-to-noise ratio is degraded further by the factor[7]

$$\sqrt{\frac{\overline{M}^2}{\overline{\overline{M^2}}}}$$

Combining these last two factors, letting

$$K'^2 = \frac{m-1}{m-1/\overline{M}} \times \frac{\overline{M}^2}{\overline{\overline{M^2}}} \qquad (9)$$

an expression for the square of the signal-to-noise ratio of a multiplier photo tube is obtained from equations 8 and 9:

$$s^2 = \frac{I_0^2}{i^2} = \frac{I_0}{2e\Delta f} K'^2 = \frac{K^2}{\Delta f} \qquad (10)$$

the last member coming from equation 2.

It is concluded that

$$K = K'\sqrt{\frac{I_0}{2e}} \qquad (11)$$

But $I_0 = \sigma L$ where σ is the cathode luminous sensitivity (amperes per lumen) and L is the luminous flux, and therefore

$$K = K'\sqrt{\frac{\sigma L}{2e}} \qquad (12)$$

Optical Considerations

Now, consider the optical parameters, i.e., the velocity of the slit image v, the trigger slit width d, its height h, the distance from the rotating mirror to the trigger slit D, and the area of the exit pupil A of the imaging lens.

The total flux of the photocell[8] is given by

$$L = \pi B \sin^2 \theta \eta A_s = B\frac{A}{D^2}\eta h d \qquad (13)$$

where B is the source brightness (candles per square millimeter); A_s is the slit area $h \times d$; θ is the angle subtended by the radius of the exit pupil, area A, at the slit; and η is the optical efficiency of the system (taking account of stray reflection and absorption of light). The third member is obtained by substituting

$$\sin^2 \theta = \frac{r^2}{D^2} = \frac{A}{\pi D^2}$$

Therefore

$$K^2 = K'^2 \frac{\sigma B A \eta h d}{2eD^2} = C_1 \frac{d}{D^2} \qquad (14)$$

where

$$C_1 = \frac{1}{2}\sigma B A \eta h K'^2/e \qquad (15)$$

Also, from the geometry of Fig. 1 and assuming a perfect slit image

$$\tau_0 = \frac{d}{v} = d/2\pi\omega D = C_2\frac{d}{D} \qquad (16)$$

where $C_2 = 1/2\pi\omega$ and ω = angular velocity of the beam = twice the angular velocity of the reflector.

Then

$$\Delta t_{\min}^2 = 0.7\tau_0/K^2 = \frac{0.7C_2 d/D}{C_1 d/D^2} = C_3^2 D$$

and it is concluded that

$$\Delta t_{\min} = C_3\sqrt{D} \qquad (17)$$

where

$$C_3 = \sqrt{\frac{0.7C_2}{C_1}} = \sqrt{\frac{0.7 \times 2e}{2\pi\omega\sigma B A \eta h K'^2}} = \frac{\sqrt{0.7}}{\sqrt{\pi}K'} \times \frac{\sqrt{e}}{\sqrt{\omega\sigma B A \eta h}} = \frac{5 \times 10^{-10}}{\sqrt{\omega\sigma B A h}} \qquad (18)$$

taking $e = 1.6 \times 10^{-19}$ and usual values for K' and η (approximately 0.5 for both). This result, equation 17, namely that the jitter is directly proportional to the square root of the optical path length, is significant. The engineer might be tempted to increase the path length for increased velocity of the slit image to obtain more accurate triggering, but this gain is in fact vitiated by the reduced light intensity.

Also interesting is the fact that the jitter is independent of the slit width, assuming, of course, that this is wide enough to put the phototube into the proper operating range. It should be noted that this derivation assumes a perfect optical design, and a light source of any desired dimension.

Conclusions

ELECTRONIC

It was found that the bandwidth of the circuitry associated with the multiplier phototube should be such that the rise time of a square pulse fed into it should equal the optical rise time, i.e., bandwidth = 0.35/optical rise time.

Under these conditions the resulting trigger jitter will be directly proportional to the square root of the optical rise time and inversely proportional to the signal-to-noise ratio at unity bandwidth. This will be true for regions where the noise may be considered white.

OPTICAL

With a given optical system, light source, multiplier photo tube, and angular velocity of reflector, the jitter will be proportional to the square root of the distance from the reflector to the phototube slit. This will be true if operation is at a light level sufficiently high so that only shot noise is important, and sufficiently low to maintain the tube in its linear operating range which extends over a region 1,000,000:1.[4]

The slit width used appears, then, to have no effect on jitter. It is limited only by other design parameters and its upper limit is determined by space limitations, available source area, and relative lens apertures. The lower limit is set by the circles of confusion which make up the slit image. (As a result of lens aberrations and diffraction effects, a lens images an object point as a disk. This disk is called circle of confusion.) When the diameter of these circles becomes comparable in size to the slit image, the quantitative optical analysis breaks down, because the optical rise time is then no longer given by equation 16 nor the image brightness by equation 13.

Also, it is seen that increasing any of the following factors will decrease jitter by a factor proportional to the square root of the increase.

1. Source brightness.
2. Angular velocity of the reflector.
3. Area of the exit pupil.
4. Height of slit (or slit image).
5. Photo cathode sensitivity.

Since other factors affecting rise time and jitter have been ignored, it is important that the associated electronic circuitry be reasonably noisefree and that a good lens design providing a well-corrected slit image be used. Also the near stationary exit pupil should be imaged on the photo cathode, so that a comparably stationary area there is illuminated. In this way, effects of nonuniformities of the cathode sensitivity are minimized.

Appendix

The illumination range over which a multiplier phototube is superior to a simple phototube may be determined as follows:

It is seen that the use of a multiplier phototube reduces considerably the effect of Johnson noise, but aggravates the shot noise somewhat.

The break-even point, i.e., the light level at which the signal-to-noise obtainable with the two types of tube is the same, may readily be determined as follows. The signal-to-noise ratios obtainable from simple and multiplier phototubes, respectively, are

$$s_0 = \frac{RI}{n_j + n_s} = \left(\frac{MRI}{Mn_j + Mn_s}\right) \qquad (19)$$

and

$$s_m = \frac{MRI}{n_j + \frac{Mn_s}{K'}} \qquad (20)$$

where R is the output resistance of the phototube, n_j is the Johnson noise, independent of cathode current I, and n_s is the shot noise proportional to $\sqrt{I}$. $1/K'$ is, as before, a factor representing the increase in noise in a multiplier phototube due to various minor factors such as shot noise at the dynodes and nonuniform multiplication across the cathodes' surface.

Clearly, the break-even point occurs when

$$Mn_j + Mn_s = n_j + \frac{1}{K'}Mn_s$$

or

$$\frac{n_j}{n_s} = \frac{\frac{1}{K'} - 1}{1 - \frac{1}{M}} \doteq \frac{1}{K'} - 1 \qquad (21)$$

If it is again assumed that $K' = 0.5$, the break-even point occurs when $n_j = n_s$. But $n_j^2 = 4kTR\Delta f$ and $n_s^2 = 2R^2eI\Delta f$, so that the foregoing requirement reduces to

$$\frac{2kT}{eR} = I = \sigma L$$

or

$$L = \frac{2kT}{\sigma eR} = 5.14 \times 10^6/R\sigma \text{ lumen} \qquad (22)$$

at room temperature, where $T = 300$ (Boltzmann's constant $k = 1.37 \times 10^{-16}$ and $e = 1.6 \times 10^{-19}$).

The maximum value of R will, of course, be determined by the interelectrode capacitances of the phototube and the bandwidth requirement.

If the design is limited to $R = \frac{1}{2\pi fC}$, equation 22 reduces to

$$L = 3.23 \times 10^6 fC/\sigma \qquad (23)$$

This result shows that in all practical cases a multiplier phototube will provide the higher signal-to-noise ratio as long as its anode ratings permit it to be operated with appreciable multiplication.

Impedance of Thin-Wire Loop Antennas

JAMES E. STORER
NONMEMBER AIEE

THE THIN-wire loop is one of the first antennas to receive theoretical consideration, having been discussed by Pocklington[1] in 1897. Pocklington treated a closed loop excited by a plane wave; he obtained an exact solution for the current on the loop in the form of a Fourier series. More recently, Hallén[2] considered a driven loop and obtained a solution, again in the form of a Fourier series, for the current and the impedance. However, Hallén pointed out that the coefficients of this series contained a singularity which made the series only quasiconvergent and hence useful only for loops small in comparison to a wave length. Moreover, the individual terms were complicated and their evaluation and a summation involved a somewhat difficult numerical task.

More recently, in an effort to obtain numerical results, other authors have dealt with the problem using approximation methods. Chang,[3] for example, applied the Hallén-King-Middleton expansion, Schelkunoff[4] has used a guided mode approximation; and the author has used a variational approach (unpublished). All of these approximation methods have one feature in common; they yield results which are in good agreement qualitatively with experiment, but poor agreement quantitatively. (It is quite possible that all of these methods, particularly Chang's could be made to yield better results by going to higher degrees of approximation; the resulting numerical labor, however, is likely to be prohibitive.) The reason for this can be explained by noting that all the approximation methods require some assumption as to the current distribution around the loop. The most common assumption is that the current distribution approximates a sinusoidal distribution. As will be shown subsequently, the sinusoidal assumption is not satisfactory, particularly for the current near the driving point of the antenna.

In this paper the rigorous Fourier series solution obtained by Hallén is reexamined, and modified so that the convergence difficulties which he encountered are avoided. Extensive numerical results are presented in Appendix I for the impedances of loops for varying wire sizes and circumferences up to $2^1/_2$ wave lengths. Appendix II presents some curves which aid in the computation of field patterns and current distributions. For an antenna having a particular wire size, some experimentally measured impedances are presented which agree well with theory.

Fourier Series Solution for the Current Distribution

Integral equations for the current distribution on thin-wire antenna structures are readily obtained by expressing the electric field as a function of the current, through Helmholtz integrals, and then equating the total electric field to zero along the wire surface. Following this procedure, with harmonic time dependence of the form $\epsilon^{+j\omega t}$, and with co-ordinate system and dimensions as indicated in Fig. 1, the integral equation for the circular loop antenna can be written as

$$V\delta(\phi) = \frac{j\zeta_0}{4\pi}\int_{-\pi}^{\pi} K(\phi-\phi')I(\phi')d\phi' \qquad (1)$$

where $I(\phi)$ is the total current at ϕ on the loop; V is the voltage of the slice generator exciting the loop at $\phi=0$; $\delta(\phi)$ is the

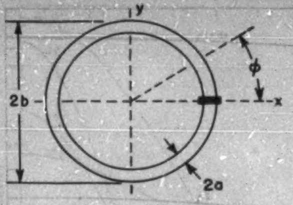

Fig. 1. Co-ordinates for loop antenna

Dirac delta function; and $k=\omega/c=2\pi/\lambda$; $\zeta_0=\sqrt{\frac{\mu_0}{\epsilon_0}}=120\pi$ ohms. The kernel of the integral equation 1 is given explicitly by

$$K(\phi-\phi')=\left[kb\cos(\phi-\phi')+\frac{1}{kb}\frac{\partial^2}{\partial\phi^2}\right]\times\frac{\epsilon^{-jkbR(\phi-\phi')}}{R(\phi-\phi')} \qquad (2A)$$

$$R(\phi-\phi')=\left[4\sin^2\left(\frac{\phi-\phi'}{2}\right)+a^2/b^2\right]^{1/2} \qquad (2B)$$

where a is the radius of the wire and b is the radius of the loop.

The thin-wire assumption, which provides the basis for obtaining this one-dimensional current equation, can be expressed explicitly as $a^2<<b^2$, $k^2a^2<<1$. The resulting solution cannot be more accurate than the order of these approximations.

Since $\frac{1}{R(\phi-\phi')}\epsilon^{-jkbR(\phi-\phi')}$ is a bounded, periodic function of ϕ, it can be expanded into a Fourier series, i.e.

$$\frac{1}{R(\phi-\phi')}\epsilon^{-jkbR(\phi-\phi')}=\sum_{-\infty}^{\infty}K_n\epsilon^{-jn(\phi-\phi')} \qquad (3)$$

$$K_n=K_{-n}=\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{\epsilon^{-jkbR(\phi)}}{R(\phi)}\epsilon^{-jn\phi}d\phi \qquad (4)$$

Using equation 3 together with equation 2, it is seen that

$$K(\phi-\phi')=\sum_{-\infty}^{\infty}\alpha_n\epsilon^{jn(\phi-\phi')} \qquad (5)$$

where

$$\alpha_n=\alpha_{-n}=kb\left\{\frac{K_{n+1}+K_{n-1}}{2}\right\}-\frac{n^2}{kb}K_n \qquad (6)$$

Inserting expression 5 into integral equation 1 yields

$$V\delta(\phi)=\frac{j\zeta_0}{4\pi}\sum_{-\infty}^{\infty}\alpha_n\int_{-\pi}^{\pi}\epsilon^{jn(\phi-\phi')}I(\phi')d\phi' \qquad (7)$$

After expanding $I(\phi)$ into a Fourier series

$$I(\phi)=\sum_{-\infty}^{\infty}I_n\epsilon^{jn\phi};\quad I_n=\frac{1}{2\pi}\int_{-\pi}^{\pi}I(\phi)\epsilon^{-jn\phi}d\phi \qquad (8)$$

it can be seen that equation 7 reduces to the following

$$V\delta(\phi)=\frac{j\zeta_0}{2}\sum_{-\infty}^{\infty}\alpha_nI_n\epsilon^{jn\phi}$$

Hence

$$I_n=\frac{1}{j\pi\zeta_0\alpha_n}\int_{-\pi}^{\pi}\epsilon^{-jn\phi}V\delta(\phi)d\phi=\frac{V}{j\pi\zeta_0\alpha_n}$$

Inserting this result into equation 8 yields

$$I(\phi)=\frac{V}{j\pi\zeta_0}\sum_{-\infty}^{\infty}\frac{\epsilon^{jn\phi}}{\alpha_n}=\frac{V}{j\pi\zeta_0}\times\left(\frac{1}{\alpha_0}+2\sum_{1}^{\infty}\frac{\cos n\phi}{\alpha_n}\right) \qquad (9)$$

From this, the impedance of the antenna Z is found to be

$$Z=\frac{V}{I(0)}=j\pi\zeta_0\left(\frac{1}{\alpha_0}+2\sum_{1}^{\infty}\frac{1}{\alpha_n}\right)^{-1} \qquad (10)$$

These results, equations 9 and 10, obtained by Hallén, constitute a formal solution of the loop antenna. From them the transmitting pattern and by reciprocity the receiving pattern can be obtained. However, in order to make them useful, some way must be found to evaluate the series numerically.

It can be shown that these equations, 9 and 10, are in agreement with the theory of small loops. If equation 4 is used and the explicit evaluation of K_n given in Appendix III, it is readily shown that, for loops small in comparison to the wave length, the current is nearly a constant, independent of ϕ and

$$kb\ll 1,\ Z\cong j\pi\zeta_0\alpha_0=j\pi\zeta_0kbK_1$$

$$\cong\frac{\pi\zeta_0}{6}k^4b^4+j\pi\zeta_0kb\left(\ln\frac{8b}{a}-2\right)$$

This is the usual equation for the resistance and reactance of a small loop.

The Fourier Series

It is apparent from the preceding derivation that the usefulness of this method of solution depends on the evaluation of the series

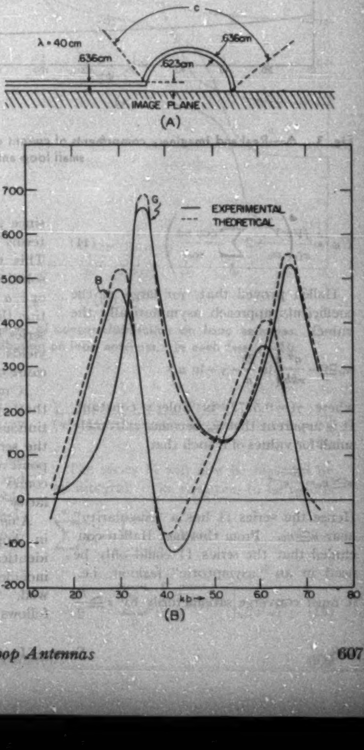

Fig. 2. A—Experimental dimensions. B—Impedance of loop antenna

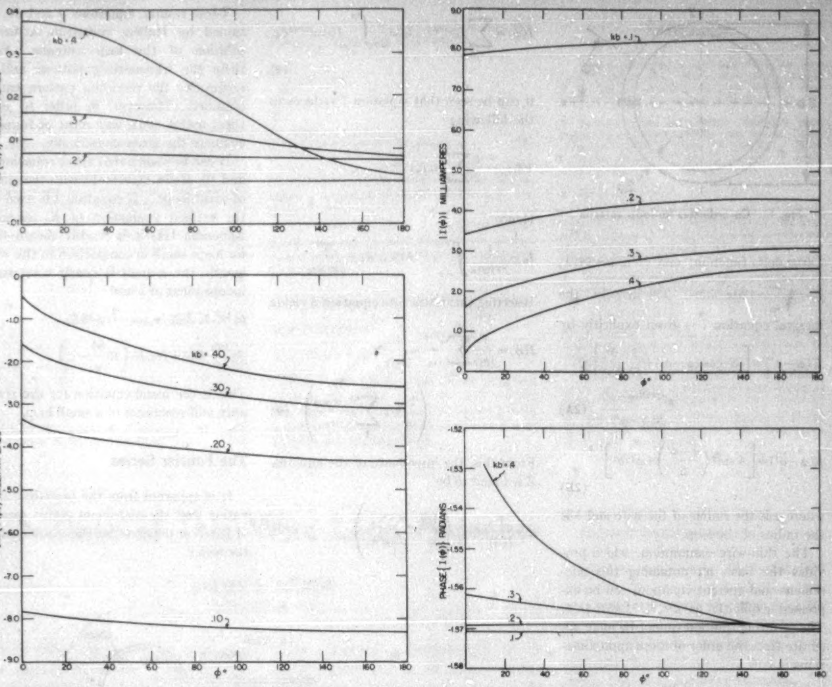

Fig. 3. A—Real and imaginary components of current distribution on small loop antennas; B—Magnitude and phase of current distribution on small loop antennas. In each case $\Omega = 2\ln(2\pi b/a) = 10$

$$I(\phi)=\frac{jV}{\pi\zeta_0}\left(\frac{1}{\alpha_0}+2\sum_{1}^{\infty}\frac{\cos n\phi}{\alpha_n}\right) \qquad (11)$$

Hallén proved that, for large n, the coefficients approach asymptotically the value.

$$\alpha_n \cong -\frac{n^2}{\pi kb}\left\{\ln\frac{2b}{a}-\gamma-\ln n\right\}$$

where $\gamma(=0.5772)$ is Euler's constant. It is apparent that α_n becomes extremely small for values of n such that

$$n \cong n_0=\frac{2b}{a}\epsilon^{-\gamma}$$

Hence the series 11 has a "singularity" near $n \cong n_0$. From this fact Hallén concluded that the series 11 could only be used in an "asymptotic" fashion, i.e., it must converge satisfactorily by $r \cong \frac{n_0}{2}$ since' after this, the value of the individual terms begin increasing in magnitude. This restriction meant that the series solution 11 was only useful for kb small or b/a very large. Even with this limitation the summation of $n_0/2$ terms of this series in a formidable task and, at best, yields relatively inaccurate results because of the "singularity."

It must be remembered at this point that current is both bounded and continuous (for physical reasons) and hence the series 11 must converge. When this point of view is adopted, the problem becomes one of treating Hallén's "singularity" in a more rigorous fashion.

A derivation of the value of αn is given in Appendix III, which is essentially identical to that of Hallén's, but which includes the dominant complex term as well. The result for large n is given as follows

$$\alpha_n \sim \frac{1}{\pi}\left(kb-\frac{n^2}{kb}\right)\left(\ln n_0-\ln n-j\times\frac{(kb)^{2n+1}}{\Gamma(2n+2)}\right) \quad \begin{matrix} n>kb \\ n\gg 1\end{matrix} \qquad (12)$$

where $n_0=\frac{2b}{a}\epsilon^{-\gamma}$

It is apparent that the inclusion of the rather negligible complex term in equation 12 cannot alter significantly the sum of the resulting series. However, with its inclusion α_n is never equal to zero. This fact will be used subsequently to permit a replacement of the series by an integral.

The following work will be restricted to loops in which $kb<2.5$, i.e., the circumference of the loop is less than $2\frac{1}{2}$ wave lengths. (The derivation can readily be modified to include values of kb larger than 2.5 if desired.) Almost all loop antennas of practical interest are contained

Vol. 7
Pt. 1
1956

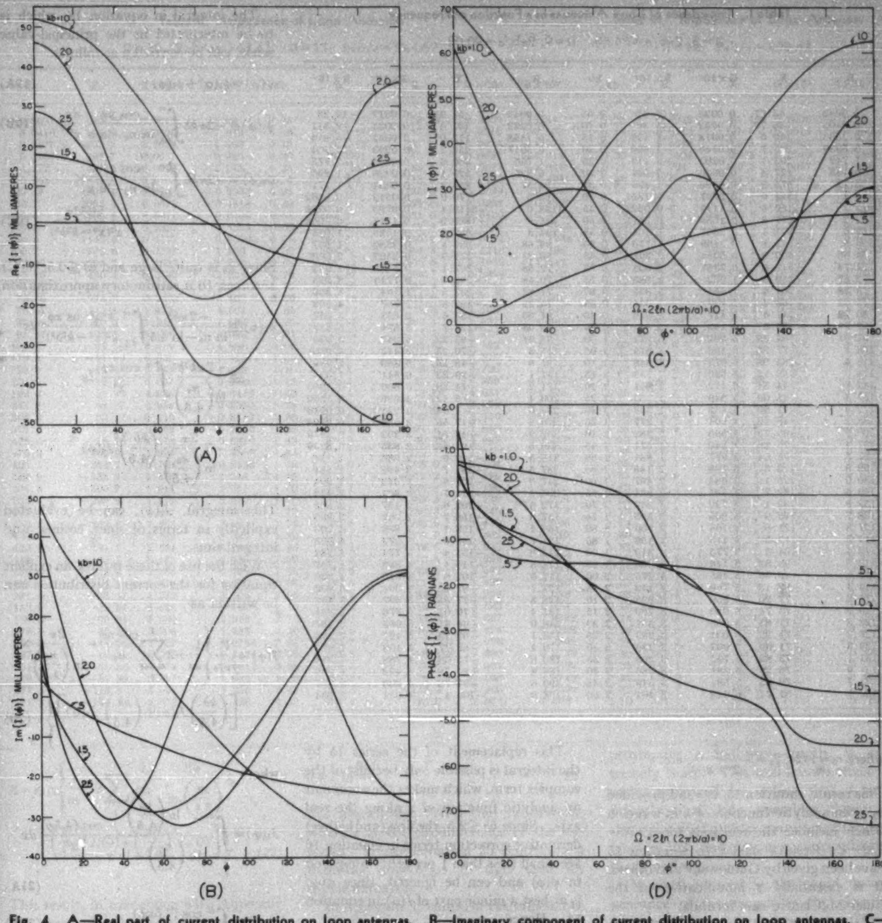

Fig. 4. A—Real part of current distribution on loop antennas. B—Imaginary component of current distribution on loop antennas. C—Magnitude of current distribution on loop antennas. D—Phase of current distribution on loop antennas. In each case $\Omega=10$

in this range. The series 11 can then be written in the form

$$I(\phi)=\frac{V}{j\pi\zeta_0}\left(\frac{1}{\alpha_0}+2\sum_{1}^{4}\frac{\cos n\phi}{\alpha_n}+\psi(\phi)\right) \qquad (13)$$

where

$$\psi(\phi)=2\sum_{5}^{\infty}\frac{\cos n\phi}{\alpha_n}$$

The procedure to be used will sum the first five terms of the series explicitly, and replace the remainder of series $\psi(\phi)$ by an integral.

Now, it can be shown by an insertion of numerical values that for $kb \leqq 2.5$ and $n \geqq 5$, the value of α_n differs negligibly from the asymptotic value given by equation 12. Hence, to an excellent approximation

$$\psi(\theta)=-2\pi kb\sum_{5}^{\infty}\times$$

$$\frac{\cos n\phi}{(n^2-k^2b^2)[\ln n_0-\ln n-j(kb)^{2n+1}/\Gamma(2n+2)]} \qquad (14)$$

The series 14 will now be replaced by an integral. The equation to be used is

$$\sum_{N}^{\infty}a_n=\int_{N-1/2}^{\infty}a_x dx+\sum_{0}^{\infty}c_n\left[\frac{d^{2n+1}}{dx^{2n+1}}a_x\right]_{x=N-1/2} \qquad (15)$$

where $c_0=1/24$, $c_1=-\dfrac{7}{2^4\times360}$, etc.

This result, equation 15, is valid provided a_n is an analytic function of n in a region which includes the real axis for $n>N-1/2-\epsilon$. Results similar to equation 15 have been given by Gumowski[5] and others. It is essentially a modification of the Euler-McClaurin sum formula.

Using equation 15 in connection with equation 14 yields

$$\psi(\phi)=-2\pi kb\int_{4.5}^{\infty}\times\frac{\cos x\phi dx}{(x^2-k^2b^2)\left(\ln n_0-\ln x-j\dfrac{(kb)^{2n+1}}{\Gamma(2x+2)}\right)}\tag{16}$$

$$-\frac{2\pi kb}{24}\times\left[\frac{d}{dx}\frac{\cos x\phi}{(x^2-k^2b^2)\left(\ln n_0-\ln x-j\dfrac{(kb)^{2x+1}}{\Gamma(2x+2)}\right)}\right]_{x=4.5}-\cdots$$

This replacement of the series 15 by the integral is possible only because of the complex term, which makes the argument an analytic function of x along the real axis. Since $kb\leqq2.5$, the first (and higher) derivative correction terms in equation 16 are small (less than 1 per cent) compared to $\psi(\phi)$ and can be ignored, since $\psi(\phi)$ is at best a minor part of $I(\phi)$ in equation 14. Hence,

$$\psi(\phi)=-2\pi kb\int_{4.5}^{\infty}\times\frac{\cos x\phi dx}{(x^2-k^2b^2)\left(\ln n_0-\ln x-i\dfrac{(kb)^{2x+1}}{\Gamma(2x+2)}\right)}\tag{17}$$

Next, it can readily be shown that the complex term in the integral of equation 17 can also be ignored. This yields

$$\psi(\phi)=-2\pi kb\int_{4.5}^{\infty}\frac{\cos x\phi dx}{(x^2-k^2b^2)(\ln n_0-\ln x)}\tag{18}$$

The integral in equation 18, which is to be interpreted in the principal-value sense, can be rewritten as follows

$$\psi(\phi)=\psi_1(\phi)+\psi_2(\phi)\tag{19A}$$

$$\psi_1(\phi)=-2\pi kb\int_{4.5}^{\infty}\frac{\cos x\phi}{\ln n_0-\ln x}\frac{dx}{x^2}\tag{19B}$$

$$\psi_2(\phi)=-2\pi kb\int_{4.5}^{\infty}\frac{\cos x\phi}{\ln n_0-\ln x}\times\frac{k^2b^2dx}{x^2(x^2-k^2b^2)}\tag{19C}$$

Since n_0 is quite large and $kb\leqq2.5$, 19(C) becomes, to a satisfactory approximation

$$\psi_2(\phi)\cong\frac{-2\pi kb}{\ln n_0-\ln 4.5}\int_{4.5}^{\infty}\frac{k^2b^2\cos x\phi}{x^2(x^2-k^2b^2)}dx$$

$$\cong\frac{-2\pi k^3b^3}{\ln\left(\dfrac{n_0}{4.5}\right)}\int_{4.5}^{\infty}\frac{\cos x\phi}{x^4}dx$$

$$=-\frac{2\pi}{\ln\left(\dfrac{n_0}{4.5}\right)}\left(\frac{kb}{4.5}\right)^3J_2(\phi)$$

This integral, $J_2(\phi)$, can be evaluated explicitly in terms of sines, cosines, and integral sines.

With the use of these results, an explicit equation for the current distribution can be written as

$$I(\phi)=\frac{V}{j\pi\zeta_0}\left\{\frac{1}{\alpha_0}+2\sum_1^4\frac{\cos n\phi}{\alpha_n}-\frac{2\pi}{\ln\left(\dfrac{n_0}{4.5}\right)}\times\left[\left(\frac{kb}{4.5}\right)J_1(\phi)+\left(\frac{kb}{4.5}\right)^3J_2(\phi)\right]\right\}\tag{20}$$

where

$$J_1(\phi)=\int_1^{\infty}\frac{\ln\left(\dfrac{n_0}{4.5}\right)}{\ln\left(\dfrac{n_0}{4.5}\right)-\ln x}\frac{\cos(4.5\phi)}{x^2}dx\tag{21A}$$

$$J_2(\phi)=\int_1^{\infty}\frac{\cos(4.5x\phi)}{x^4}dx\tag{21B}$$

$n_c=\dfrac{2b}{a}\epsilon^{-\gamma}$ and explicit equations for the α_n are given in Appendix III.

Note that the $J_k(\phi)$ integrals have only appreciable values near $\phi=0$. (An asymptotic equation for them, when $\phi>1$, can readily be obtained.) They cannot be approximated satisfactorily by a sinusoid and they are a partial explanation of why approximate methods of dealing with the loop antenna do not yield good quantitative results.

The equation for the impedance of the loop antenna becomes

$$Z=j\pi\zeta_0\left\{\frac{1}{\alpha_0}+2\sum_{1}^{4}\frac{1}{\alpha_n}-\frac{2\pi}{\ln\left(\frac{n_0}{4.5}\right)}\times\left[\left(\frac{kb}{4.5}\right)J_1(0)+\left(\frac{kb}{4.5}\right)^3J_3(0)\right]\right\}^{-1}\qquad(22)$$

This result, in connection with Appendix III, forms the basis for the impedance tables presented in Appendix I. The quantities $J_k(0)$ are explicitly given by the equation

$$J_1(0)=\frac{\ln\left(\frac{n_0}{4.5}\right)}{\left(\frac{n_0}{4.5}\right)}\int_{-\infty}^{\ln\left(\frac{n_0}{4.5}\right)}\frac{e^{+x}}{x}\,dx$$

$$J_3(0)=1/3$$

Results

The impedance of loop antennas for various values of b/a have been calculated with the use of equation 22. As a parameter, the quantity

$$\Omega=2\ln\frac{2\pi b}{a}\qquad(23)$$

has been chosen. Note that $2\pi b/a=c/a$, where c is the circumference of the antenna. Hence equation 23 represents a definition analogous to that used for dipole antennas.

In Appendix I, values of the impedance are tabulated for $0\leqq kb\leqq2.5$ and $\Omega=8$, 9, 10, 11, 12. They are also presented in graphic form. These impedances are useful for examining the operation of a loop antenna as a function of frequency. For laboratory purposes, however, it is sometimes convenient to have tables available appropriate to holding the frequency fixed and varying the size of the antenna. These tables, given in Appendix I, have been obtained by interpolation from the earlier tables.

It is perhaps worth while to comment on some of the more obvious features of these loop antenna impedances. As can be seen, the first antiresonance, occurring when the circumference of the loop approximates a half-wave-length, is extremely sharp. This well-known effect is easily explained by noting that a sufficiently small loop resembles closely a short-circuited quarter-wave-length transmission line and has a correspondingly sharp antiresonance.

Of equal interest is the rapid disappearance of resonances as the circumference of the antenna increases. Thus, for $\Omega\leqq9$, a second resonance point does not even exist. If one compares these impedances with those for a dipole antenna, it is seen that the two are similar, both qualitatively and quantitatively, for $c>\lambda$. The prime difference is that the loop is essentially more capacitive (by about 130 ohms) than a dipole. This can be explained on the basis that changed surfaces are closer together on a loop than on a dipole. This shift in reactance level by 130 ohms permits the dipole to have several resonances and antiresonances, whereas, as noted previously, a moderately thick loop ($\Omega<9$) has essentially

(*Continued on page 615*)

only one antiresonance. The resistance curves for the loop and dipole are very similar, with the resistance minima having almost identical values.

It is interesting to compare these theoretical loop impedances with some experimentally measured ones. Miss Phyllis Kennedy of Cruft Laboratory has measured some loop impedances, using a half-loop over an image plane, and driven by a 2-wire line. The explicit configuration is indicated in Fig. 2(A). One set of the admittances measured by Miss Kennedy appears in Fig. 2(B) together with the corresponding theoretical curves. The agreement between the theoretical and experimental curves is seen to be excellent. It is seen that the resistance peaks near resonance on the theoretical conductance curves are slightly higher than those on the experimental curve. This could have been anticipated, as ohmic losses of the loop were not taken into account in the theoretical solution. The two susceptance curves differ by a slight additive amount throughout the entire range. This can readily be attributed so the so-called end effect of the feeding line, which arises from coupling the fact that the transmission-line excitation differs from the "slice generator" used in the theoretical model. King[4] has calculated this end effect for a dipole antenna. The dominant correction term is a negative capacitance in shunt with the antenna. Quite obviously, the end correction for a loop antenna should be similar, even to the order of magnitude. If such an approximate correction is made to the susceptance curve of Fig. 2(B), this is changed in the right direction.

In Appendix II, values of the quantities $1/\alpha_k$ and the functions $J_k(\phi)$ are presented graphically to facilitate evaluation of the current distribution using equations 20 and 21. To obtain an idea of the type of current distributions on loop antennas, some were calculated for the explicit case of $\Omega=10$. Because the $J_k(\phi)$ were evaluated by numerical integration, there exists a slight discrepancy between $I(0)$ and the admittance. Since the admittance values are more accurate, they were used in place of $I(0)$.

One of the classic assumptions in antenna literature is that a small loop has a constant current distribution. To examine the validity of the assumption, the actual current distributions were calculated for $\Omega=10$ and $kb=0.1$, 0.2, 0.3, and 0.4. These appear in Fig. 3. It is apparent that for the smallest loop, $kb=0.1$, the current varies in magnitude by about 5 per cent and hence can be considered reasonably constant. For $kb=0.2$, however, the variation is well over 10 per cent. On the basis of these results, one would be led to the conclusion that loops much larger than $kb=0.2$ cannot be considered small.

To obtain an idea of how the distribu-

tion of current varies as the loop size increased, values of it were calculated for $\Omega=10$ and $kb=0.5$, 1.0, 1.5, 2.0, and 2.5. These results appear in Fig. 4. Perhaps the most noticeable feature in these curves appears in the plots of magnitude and phase for the larger values kb. For values of $\phi<90$ degrees, it is apparent that the current distribution is beginning to approximate a traveling wave, in the sense that variations in the magnitude have been reduced and the phase is becoming linear. This is in agreement with the observation made in connection with the impedances, namely, that for larger kb the magnitude of the variation of the resistance is reduced.

Appendix I. Input Impedance of Loop Antennas

In Tables I through V impedances, $Z=R+jX$, are given in ohms and admittances, $Y=1/Z=G+jB$, are given in mhos. The loop radius is designated by b and the loop wire radius by a. The ratio b/a is expressed in terms of the parameter $\Omega=\ln 2\pi b/a$. Note that $2\pi b=c$, the circumference of the loop, and $kb=2\pi b/\lambda=c/\lambda$, where λ is the wave length. Thus kb is simply the circumference of the loop divided by the wave length.

The input impedance as a function of frequency is shown in graph form in Figs. 5 through 9 as follows:

Fig. 5: R versus kb for $\Omega=8, 9, 10, 11, 12$; $kb \leqq 2.5$.
Fig. 6: X versus kb for $\Omega=8, 9, 10, 11, 12$; $kb \leqq 2.5$.
Fig. 7: G versus kb for $\Omega=8, 9, 10, 11, 12$; $kb \leqq 2.5$.
Fig. 8: B versus kb for $\Omega=8, 9, 10, 11, 12$; $kb \leqq 2.5$.
Fig. 9: Locus of resonance and antiresonance points.

Tables I through III show input impedance and admittance as a function of frequency, as follows:

Table I: Z and Y versus kb for $\Omega=8, 9$; $kb \leqq 2.5$.
Table II: Z and Y versus kb for $\Omega=10, 11$; $kb \leqq 2.5$.
Table III: Z and Y versus kb for $\Omega=12$; $kb \leqq 2.5$.

Tables IV and V show input impedance for ka constant, as follows:

Table IV: Z versus kb for $a=3/16$ inch, 1/4 inch, 5/16 inch, at $\lambda=100$ cm (centimeters).
Table V: Z versus kb for $a=3/8$ inch, 1/2 inch, 3/4 inch, at $\lambda=100$ cm.

Appendix II. Graphs to Facilitate Evaluation of Current Distribution on a Loop Antenna

The current distribution on a loop antenna is given explicitly by equation 20

$$I(\phi)=\frac{V}{j\pi\zeta_0}\left\{\frac{1}{\alpha_0}+2\sum_{1}^{4}\frac{\cos n\phi}{\alpha_n}-\frac{2\pi}{\ln\frac{n_0}{4.5}}\times\left[\left(\frac{kb}{4.5}\right)J_1(\phi)+\left(\frac{kb}{4.5}\right)^3 J_2(\phi)\right]\right\}_{kb\leqq 2.5} \quad (20)$$

where

V is the voltage driving the antenna
$\zeta_0=120$ ohms
a = radius of antenna wire
b = radius of antenna
$k=\omega/c=2\pi/\lambda$

$$\ln(n_0/4.5)=\frac{\Omega}{2}-3.226$$

$$\Omega=2\ln\frac{2\pi b}{a}$$

To facilitate evaluation of this equation, consult Figs. 10 through 19.

Appendix III. Evaluation of K_n

From equation 4 it is seen that

$$\Delta_n=K_{n+1}-K_n=\frac{1}{2\pi}\times\int_0^{2\pi}\frac{\epsilon^{-jkbR(\phi)}}{R(\phi)}[\epsilon^{j(n+1)\phi}-\epsilon^{jn\phi}]d\phi \quad n>0$$

$$=\frac{1}{2\pi}\int_0^{2\pi}\frac{\epsilon^{-jkbR(\phi)}}{R(\phi)}\epsilon^{j\left(n+\frac{1}{2}\right)\phi}2j\sin\phi/2d\phi$$

The "thin-wire" approximation is that $k^2a^2<<1$, $a^2<<b^2$. Neglecting terms of this order of magnitude yields

$$\Delta_n=\frac{1}{2\pi}\int_0^{2\pi}\frac{\epsilon^{-jkb\sin\phi/2}}{2\sin\phi/2}\epsilon^{j\left(n+\frac{1}{2}\right)\phi}\times 2j\sin\phi/2d\phi+\text{term of order }(a^2/b^2)$$

$$=\frac{j}{\pi}\int_0^{\pi}\epsilon^{-2jkb\sin\theta+j(2n+1)\theta}d\theta$$

$$=j[J_{2n+1}(2kb)-j\Omega_{2n+1}(2kb)]$$

where

$$J_{2n+1}(x)=\frac{1}{\pi}\int_0^{\pi}\sin(x\sin\theta-(2n+1)\theta)d\theta$$

is the Bessel function of order $2n+1$, and

$$\Omega_{2n+1}(x)=\frac{1}{\pi}\int_0^{\pi}\cos(x\sin\theta-(2n+1)\theta)d\theta$$

is the Lommel-Weber function of order $2n+1$, tabulated in Janke-Emde.

Thus, the foregoing result provides a recursion formula for K_n, i.e.,

$$\Delta_n=K_{n+1}-K_n=\Omega_{2n+1}(2kb)+jJ_{2n+1}(2kb), \quad n>0$$

Therefore, all that remains to evaluate is K_0. This coefficient can be written as

$$K_0=\frac{1}{2\pi}\int_0^{2\pi}\frac{\epsilon^{-jkbR(\phi)}}{R(\phi)}d\phi$$

$$=\frac{1}{2\pi}\int_0^{2\pi}\frac{\epsilon^{-jkbR(\phi)}-1}{R(\phi)}d\phi+\frac{1}{2\pi}\int_0^{2\pi}\frac{d\phi}{R(\phi)}$$

Now

$$\frac{1}{2\pi}\int_0^{2\pi}\frac{\epsilon^{-jkbR(\phi)}-1}{R(\phi)}d\phi$$

$$=\frac{1}{2\pi}\int_0^{2\pi}\frac{\epsilon^{-2jkb\sin\phi/2}-1}{2\sin\phi/2}d\phi+\text{term }0(a^2/b^2)$$

$$=\int_0^{2kb}dx\left(-\frac{j}{\pi}\int_0^{\pi}e^{-jx\sin\phi}d\phi\right)$$

$$=-1/2\int_0^{2kb}\Omega_0(x)dx-j/2\int_0^{2kb}\times J_0(x)dx$$

It also can be shown[3]

$$\frac{1}{2\pi}\int_0^{2\pi}\frac{d\phi}{R(\phi)}=\frac{1}{\pi}\ln\frac{8b}{a}+\text{terms }0(a^2/b^2)$$

So, to the order of approximation consistent with original integral equation

$$K_0=\frac{1}{\pi}\ln\frac{8b}{a}-1/2\int_0^{2kb}\Omega_0(x)dx-j/2\int_0^{2kb}J_0(x)dx$$

$$\Delta_n=K_{n+1}-K_n=\Omega_{2n+1}(2kb)+jJ_{2n+1}(2kb)$$

Another expression, useful for determining K_n for large n, can also be found. From the foregoing it is seen that

$$K_n=K_0+\sum_0^{n-1}\Delta_n$$

Inserting the integral expressions for Δ_n yields

$$K_n=K_0+\frac{j}{\pi}\sum_0^{n-1}\int_0^{\pi}e^{-2jkb\sin\phi+j(2n+1)\phi}d\phi$$

$$=K_0+\frac{j}{\pi}\int_0^{\pi}e^{-2jkb\sin\phi}\left(\frac{e^{2jn\phi}-1}{\sin\phi}\right)d\phi$$

Inserting the value for K_0

$$K_n=\frac{1}{\pi}\ln\frac{8b}{a}+\frac{1}{2\pi}\times$$

$$\int_0^{\pi}(e^{-2jkb\sin\phi+2jn\phi}-1)\frac{d\phi}{\sin\phi}$$

$$=\frac{1}{\pi}\ln\frac{8b}{a}+\frac{1}{2\pi}\times$$

$$\int_0^{\pi}(e^{-2jkb\sin\phi}-1)\frac{e^{2jn\phi}}{\sin\phi}d\phi+\frac{1}{2\pi}\int_0^{\pi}(e^{2jn\phi}-1)\frac{d\phi}{\sin\phi}$$

$$=\frac{1}{\pi}\ln\frac{8b}{a}-\frac{1}{2}\int_0^{2kb}[\Omega_{2n}(x)+jJ_{2n}(x)]dx-\frac{2}{\pi}\sum_0^{n-1}\frac{1}{2K+1}$$

This result can be used conveniently to determine the form of K_n for large N. For $n>>kb$, the integral is small, vanishing in the limit. Thus

$$n>>1;\ n>kb,\ K_n\sim\left(\frac{1}{\pi}\ln\frac{8b}{a}-\frac{2}{\pi}\times\sum_0^{n-1}\frac{1}{2K+1}\right)-\frac{j}{2}\int_0^{2kb}J_{2n}(x)dx$$

Now, using Sterling's equation to evaluate the harmonic series, it can be shown that

$$\sum_0^{n-1}\frac{1}{2K+1}=\frac{\gamma}{2}+\frac{1}{2}\ln 4n,\ \gamma(=0.5772)\text{ is Eulers constant.}$$

Similarly, for $n>kb$

$$J_n(x)\cong\frac{1}{\Gamma(n+1)}\left(\frac{x}{2}\right)^n$$

So $K_n\sim\frac{1}{\pi}\left(\ln\frac{2b}{a}-\gamma-\ln n\right)-j\frac{(kb)^{n+1}}{\Gamma(2n+2)}\quad\begin{cases}n^2\gg 1\\ n>kb\end{cases}$

The Fourier coefficient α_n (4), can be written as

$$\alpha_n=\left(kb-\frac{n^2}{kb}\right)K_n+kb\left[\frac{\Delta_n-\Delta_n-1}{2}\right]$$

Since Δ_n vanishes for large n, the asymptotic value of α_n is given by

$$\alpha_n\sim\left(kb-\frac{n^2}{kb}\right)\left[\frac{1}{\pi}\left(\ln\frac{2b}{a}-\gamma-\ln n\right)-j\frac{(kb)^{2n+1}}{\Gamma(2n+2)}\right]\quad\begin{cases}n^2\gg 1\\ n>kb\end{cases}$$

Finally (by simple insertion of numerical values), it can be shown that for $k\leq 2.5$, and $n\geq 5$, the asymptotic value of α_n as given differs negligibly from the correct value.

Diode-Shunting in Magnetic Amplifiers

J. L. LOWRANCE
NONMEMBER AIEE

J. D. DOLAN
NONMEMBER AIEE

IN THE self-saturating type of magnetic amplifier it is desirable to bias the saturable reactor to a particular point on its hysteresis loop. Higher gain and better linearity of the transfer function can be achieved in this manner. Shunt paths around the diodes of the magnetic amplifier afford a convenient means of biasing the saturable reactors.

The basic circuit examined in this report is a conventional full-wave, push-pull magnetic amplifier. An analysis is made of the bias currents in two different circuit arrangements. The feedback effects which are found in this type of circuit are discussed and the effective feedback factors for each circuit are determined.

Various methods of obtaining bias for the saturable reactors are shown in Fig. 1. Circuits 1 and 2 of Fig. 1 offer the advantage that fewer components are required.

Terms and Symbols

B = feedback coefficient
E = supply voltage
$\hat{E}$ = peak value of supply voltage
$\bar{E}$ = average value of supply voltage
H_θ = magnetization force required to saturate the magnetic core at angle θ of half-cycle, oersteds
I_D = current through dummy load resistor after both cores have saturated
$\bar{I}_D$ = average current through dummy load resistor after both cores have saturated
I_L = load current
$\bar{I}_L$ = average value of load current over half-cycle
I_n = net control current seen by amplifier
I_s = current from signal source
K_e = open loop voltage gain
K_e' = closed loop voltage gain
K_I = open loop current gain
K_I' = closed loop current gain
l_m = effective magnetic path length of core, centimeters
N_c = control-winding turns
N_{fb} = feedback-winding turns
N_g = gate-winding turns
R_c = control-winding resistance
R_d = dynamic foreward resistance of diode
R_D = dummy load resistor

Paper 56-749, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 14, 1956; made available for printing May 8, 1956.

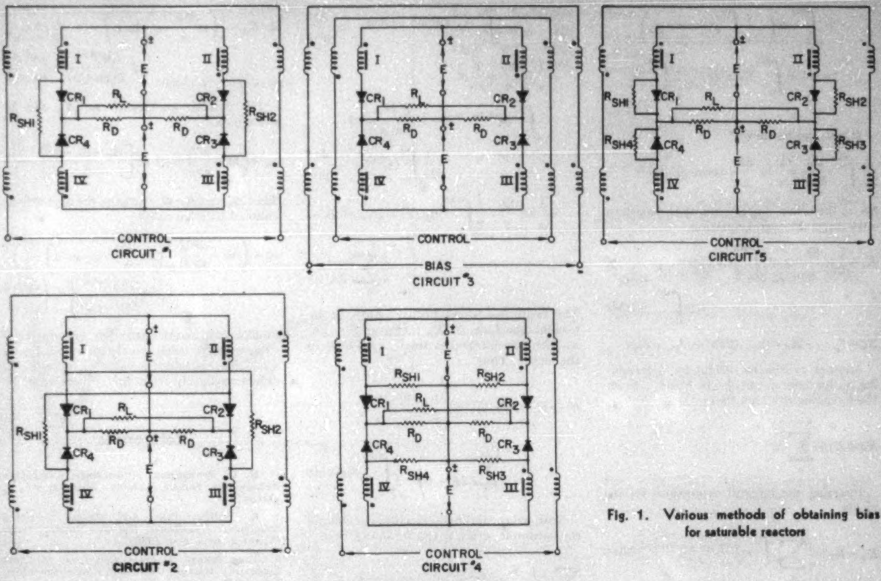

Fig. 1. Various methods of obtaining bias for saturable reactors

R_L = load resistor

R_s = signal source resistance

R_{sh} = shunt resistor

R_w = gate-winding resistance of core plus output resistance of power supply

V_{cr} = voltage across diode

$\bar{V}_{cr}$ = average voltage across diode over half-cycle

V_g = voltage absorbed by core with respect to gate winding

$\bar{V}_g$ = average value of voltage absorbed by core with respect to gate winding during half-cycle

V_{sh} = voltage across shunt resistor

$\bar{V}_{sh}$ = average voltage across shunt resistor over half-cycle

ΔV_{sh} = change in average value of voltage across shunt resistor over half cycle

Diode dynamic resistance = slope of voltage-current characteristic of diode after threshold voltage has been exceeded

Dummy load = resistors which are connected to power supply center tap from each pair of diodes

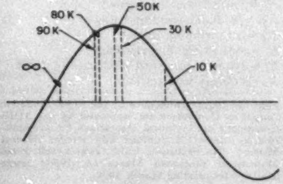

Fig. 2. Saturation angle versus shunt resistor

Gating half-cycle = interval during which supply voltage is positive with respect to anode of diode under consideration

Reset half-cycle = interval during which supply voltage is negative with respect to anode of diode under consideration

Shunt or leakage resistors = resistors which allow current to flow through gate winding during reset half-cycle

Gate winding = winding on saturable reactor which is connected to power supply

Explanation of Bias Techniques

Under conditions of no input signal the saturation angle of each core in the self-saturating type of magnetic amplifier is a function of the bias current that flows in its windings during the reset half-cycle.[1] This bias current can be supplied either by a separate winding on the core or by allowing current to flow in the reverse direction of the diode in the gate winding during the reset half-cycle. The latter method offers certain advantages because of ease in obtaining bias with little additional circuitry. This is the type of circuit considered in this report.

Under steady-state conditions, the voltage supported by a core averaged over a complete cycle is zero.

$$\int_0^{2\pi} e\,d\theta=0 \tag{1}$$

Assuming negligible excitation current, the voltage supported by the core during its gating half-cycle is equal to the integral of the supply voltage over the period before the core saturates.[2]

$$V_g=\frac{\hat{E}}{\pi}\int_0^{\theta} \sin\theta\, d\theta=\frac{\hat{E}}{\pi}(1-\cos\theta) \tag{2}$$

where $\hat{E}$ is the peak voltage and θ is the angle at which the core saturates, measured from zero with respect to the beginning of the half-cycle. Referring to equation 1, the sum of the voltages supported by the core averaged over the complete cycle is zero. Therefore the integral of the voltage absorbed by the core during the reset half-cycle can be expressed by equation 2.

$$V_g=\frac{\hat{E}}{\pi}(1-\cos\theta)$$

This may be written in terms of the average value of the supply voltage over the half-cycle.

$$V_g=\frac{E}{2}(1-\cos\theta) \tag{3}$$

As previously stated, for no-signal conditions, the angle at which the core saturates is a function of the bias current. In the case where shunt resistors are used, it is a function of the shunt resistance and the voltage across the shunt resistor.

The voltage across the shunt resistors will be analyzed in the time interval preceding and the time interval following the saturation of the cores. The first case to be considered will be for zero input signal. All cores will saturate at the same angle under this conditon.

Analysis of Shunt Voltage

Circuit 1 will be considered first.

Assume that cores 1 and 2 are positive with respect to the center tap of the power supply and cores 3 and 4 are negative with respect to this center tap.

Prior to saturation

$$\frac{E}{2}\int_0^\theta \sin\theta d\theta = V_{cr3}+V_{g3}=V_{cr4}+V_{g4} \tag{4}$$

After saturation

$$\frac{E}{2}\int_\theta^\pi \sin\theta d\theta = -I_DR_D+V_{cr3}+V_{g3}$$
$$= -I_DR_D+V_{cr4}+V_{g4} \tag{5}$$

The voltage absorbed by the core during the half-cycle is

$$\bar{V}_\theta=\frac{E}{2}(1-\cos\theta)$$

Therefore the average voltage across the diodes over the half-cycle is

$$\bar{V}_{cr3}=E+\bar{I}_DR_D-\frac{E}{2}(1-\cos\theta) \tag{6}$$

$$\bar{V}_{cr4}=E+\bar{I}_DR_D-\frac{E}{2}(1-\cos\theta) \tag{7}$$

$\bar{I}_D$ is the average value of the current flowing in the dummy load resistor of circuit 1 after both cores have saturated.

Adding the forward drop of the other diode being shunted by the shunt resistor during its gating half-cycle, the voltage across the shunt resistor becomes

$$\bar{V}_{sh1}=\frac{E}{2}(1+\cos\theta)+\bar{I}_DR_D+\bar{I}_DR_d \tag{8}$$

$$\bar{V}_{sh2}=\frac{E}{2}(1+\cos\theta)+\bar{I}_DR_D+\bar{I}_DR_d \tag{9}$$

R_d is the dynamic forward resistance of the diode.

The voltage across the dummy load resistor may be written in terms of the saturating angle θ, and the equation becomes

$$\frac{E}{2}(1+\cos\theta)=I_D(R_D+R_d+R_w)$$

$$\bar{V}_{sh1}=\bar{V}_{sh2}=\frac{E}{2}(1+\cos\theta)\times$$
$$\left(1+\frac{R_D+R_d}{R_D+R_d+R_w}\right) \tag{10}$$

For a given saturating angle and supply voltage, the value of reset magnetizing force can be calculated from the equation

$$H_\theta=\frac{0.4\pi NI}{lm} \tag{11}$$

where H_θ is the magnetizing force in oersteds and I is the magnetization current in amperes. In this case, I is the current through the shunt resistor.

The shunt resistance can be expressed in terms of the saturating angle of the core and the supply voltage

$$R_{sh1}=R_{sh2}=\frac{E(1+\cos\theta)}{\dfrac{H_\theta lm}{0.4\pi N_G}}\left(\frac{R_D+R_d+w/s}{R_D+R_d+R_w}\right) \tag{12}$$

The next step is to determine the relationship between the saturating angle and the magnetizing force. It is possible to obtain these data by empirical methods for a given core material and core geometry.[3] These data are then applicable to designs in which this type of core is used.

The change in saturation angle with various values of shunt resistors and constant supply voltage is shown in Fig. 2. These data were obtained by making measurements in the circuit and calculating the angle from the foregoing equations. Other techniques such as oscilloscope measurements and timing devices may be used to obtain the same data.[4]

An examination of circuit 2 shows that for zero signal conditions the equations for the voltage across the shunt resistors is the same as in circuit 1.

$$\bar{V}_{sh1}=\bar{V}_{sh2}=\frac{E}{2}(1+\cos\theta)+\bar{I}_DR_D+\bar{I}_DR_d \tag{13}$$

It may therefore be shown by deduction that for zero input signal conditions the two circuits are equivalent with respect to the bias circuit.

Analysis of Shunt Voltage with Input Signal

The preceding statement is true, however, only for zero input signal conditions. The circuit will now be considered for an input signal applied to the amplifier, over the linear region of the transfer function. The signal is assumed to be in sense which makes core 1 saturate before core 2. As in the previous cases, it is assumed that cores 1 and 2 are positive with respect to the power supply center tap.

CIRCUIT 1

Before core 1 saturates

$$\frac{E}{\pi}\int_0^{\theta_1}\sin\theta d\theta=V_{g1}=V_{g2}$$

$$\frac{E}{\pi}\int_0^{\theta_1}\sin\theta d\theta=V_{g3}+V_{cr3}=V_{g4}+V_{cr4}$$

After core 1 saturates but before core 2 saturates

$$\frac{E}{\pi}\int_{\theta_1}^{\theta_2}\sin\theta d\theta=V_{g1}+I_L(R_D+R_L)+$$
$$\left(\frac{2R_D+R_L}{R_D}\right)(R_w+R_d)I_L$$

$$\frac{E}{\pi}\int_{\theta_1}^{\theta_2}\sin\theta d\theta=V_{g2}+I_LR_D$$

$$\frac{E}{\pi}\int_{\theta_1}^{\theta_2}\sin\theta d\theta=V_{g3}+V_{cr3}-I_LR_D$$

$$\frac{E}{\pi}\int_{\theta_1}^{\theta_2}\sin\theta d\theta=V_{g4}+V_{cr4}-I_L(R_D+R_L)$$

After both cores have saturated

$$\frac{E}{\pi}\int_{\theta_2}^{\pi}\sin\theta d\theta=V_{g1}+I_D(R_w+R_d+R_D)$$

$$\frac{E}{\pi}\int_{\theta_2}^{\pi}\sin\theta d\theta=V_{g2}+I_D(R_w+R_d+R_D)$$

$$\frac{E}{\pi}\int_{\theta_2}^{\pi}\sin\theta d\theta=V_{g3}+V_{cr3}-I_DR_D$$

$$\frac{E}{\pi}\int_{\theta_2}^{\pi}\sin\theta d\theta=V_{g4}+V_{cr4}-I_DR_D$$

Adding the equations for the three time intervals together yields the equation for the average value of the supply voltage over the half-cycle.

$$\bar{E}=\bar{V}_{g1}+\bar{I}_L(R_D+R_L)+$$
$$\bar{I}_D(R_D+R_w+R_d)+$$
$$(R_w+R_d)\left(\frac{2R_D+R_L}{R_D}\right)\bar{I}_L \tag{14}$$

$$\bar{E}=\bar{V}_{g2}+\bar{I}_LR_D+\bar{I}_D(R_D+R_w+R_d) \tag{15}$$

$$\bar{E}=\bar{V}_{g3}+\bar{V}_{cr3}-\bar{I}_LR_D-\bar{I}_DR_D \tag{16}$$

$$\bar{E}=\bar{V}_{g4}+\bar{V}_{cr4}-\bar{I}_L(R_D+R_L)-\bar{I}_DR_D \tag{17}$$

Due to the input signal, the voltage absorbed by each core is no longer equal to the voltages absorbed by the other cores. For d-c output from the stage, cores 1 and 4 are wound in the same sense with respect to the control winding, and cores 2 and 3 are wound in the same sense, but opposite to cores 1 and 4. Therefore it may be evident that the effect of control signal upon cores 1 and 4 is equal and opposite to the effect upon cores 2 and 3.

Expressing the voltage absorbed by the core in terms of the saturating angles gives

$$\bar{E}=\frac{E}{2}(1-\cos\theta_1)+\bar{I}_L(R_D+R_L)+$$
$$\frac{2R_D+R_L}{R_D}(R_w+R_d)\bar{I}_L+$$
$$\bar{I}_D(R_D+R_d+R_w) \tag{18}$$

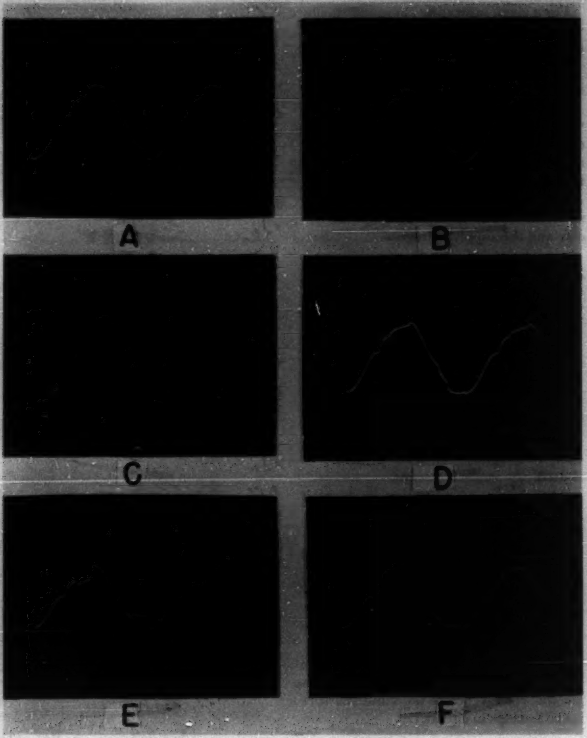

Fig. 3. Effect of control signal on shunt voltage

A—Circuit 1, voltage across R_{sh} for no-input signal
B—Circuit 2, voltage across R_{sh} for no-input signal
C—Circuit 1, voltage across R_{sh1} for an input signal positive with respect to dot
D—Circuit 2, voltage across R_{sh2} for an input signal positive with respect to the dot
E—Circuit 1, voltage across R_{sh2} for an input signal positive with respect to the dot
F—Circuit 2, voltage across R_{sh1} for an input signal positive with respect to the dot

$$\bar{E}=\frac{\bar{E}}{2}(1-\cos\theta_2)+\bar{I}_LR_D+\bar{I}_D(R_D+R_d+R_w) \tag{19}$$

$$\bar{E}=\frac{\bar{E}}{2}(1-\cos\theta_2)-\bar{I}_LR_D-\bar{I}_DR_D+\bar{V}_{cr3} \tag{20}$$

$$\bar{E}=\frac{\bar{E}}{2}(1-\cos\theta_1)-\bar{I}_L(R_L+R_D)-\bar{I}_DR_D+\bar{V}_{cr4} \tag{21}$$

Solving equations 18 and 19 for $\cos\theta_1$ and $\cos\theta_2$ and, substituting in equations 20 and 21, the voltages across diodes CR_3 and CR_4 are

$$\bar{V}_{cr3}=2\bar{I}_LR_D+\bar{I}_D(R_D+R_d+R_w) \tag{22}$$

$$\bar{V}_{cr4}=\bar{I}_L\left[\frac{2R_D+R_L}{R_D}(R_w+R_d)+2R_D+2R_L\right]+\bar{I}_D(R_D+R_d+R_w) \tag{23}$$

The voltages across the shunt resistors are

$$\bar{V}_{sh1}=\bar{V}_{cr4}+\bar{I}_LR_d\left(\frac{2R_D+R_L}{R_D}\right)+\bar{I}_DR_d \tag{24}$$

$$\bar{V}_{sh2}=\bar{V}_{cr3}+\bar{I}_DR_d \tag{25}$$

Substituting for the diode voltages from equations 22 and 23 gives

$$\bar{V}_{sh1}=\bar{I}_L\left[\frac{2R_D+R_L}{R_D}(R_w+2R_d)+2R_D+2R_L\right]+\bar{I}_D(R_D+R_w+2R_d) \tag{26}$$

$$\bar{V}_{sh2}=I_L(2R_D)+\bar{I}_L(R_D+R_w+2R_d) \tag{27}$$

From equations 26 and 27, it is seen that the voltage across the shunt resistor is a function of the load current and the current that flows in the dummy load, after both cores have saturated. Solving for the difference in the shunt voltages

$$\bar{V}_{sh1}-\bar{V}_{sh2}=\bar{I}_L\left[\frac{2R_D+R_L}{R_D}\times(R_w+2R_d)+2R_L\right] \tag{28}$$

From this equation, it is seen that the difference or unbalance in the shunt voltages is a function of the load current.

CIRCUIT 2

An examination of circuit 2 shows that the voltage appearing across the diodes may be expressed by the same equations derived for circuit 1. The voltages across the shunt resistors are

$$\bar{V}_{sh1}=-\bar{I}_LR_L+\bar{I}_DR_d+\bar{V}_{cr4} \tag{29}$$

$$\bar{V}_{sh2}=+\bar{I}_LR_L+R_d\left(\frac{2R_D+R_L}{R_D}\right)\times\bar{I}_L+R_d\bar{I}_D+\bar{V}_{cr3} \tag{30}$$

Substituting equations 22 and 23 for the diode voltages gives

$$\bar{V}_{sh1}=-\bar{I}_LR_L+\bar{I}_DR_d+\bar{I}_L\times\left[\frac{2R_D+R_L}{R_D}(R_w+R_d)+2R_D+2R_L\right]+\bar{I}_D(2R_D+R_w+R_d) \tag{31}$$

$$\bar{V}_{sh2}=+\bar{I}_LR_L+\bar{I}_DR_d+\bar{I}_L\frac{R_d}{R_D}(2R_D+R_L)+2\bar{I}_LR_D+\bar{I}_D(2R_D+R_w+R_d) \tag{32}$$

Subtracting equation 32 from 31 gives

$$\bar{V}_{sh1}-\bar{V}_{sh2}=\bar{I}_L\left(\frac{2R_D+R_L}{R_D}\right)(R_w) \tag{33}$$

As in the previous analysis of circuit 1, it is seen that the difference in shunt voltages is a function of the load current.

Explanation of Feedback Effect

It is assumed that the flux that is reset on the core during the reset half-cycle is a function of the average net ampere-turns that exist during the reset half-cycle. This is true for all practical purposes. The net ampere-turns are the algebraic sum of the control ampere-turns and the leakage ampere-turns. In the preceding mathematical analysis of the shunt voltage it is seen that a difference in shunt current exists which is a function of the amplifier output. A difference in the reset flux of cores 1 and 2

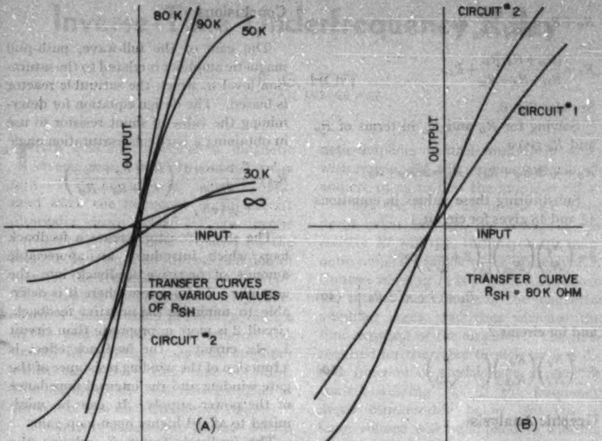

Fig. 4. Transfer curves. A—For various values of shunt resistance. B—For circuits 1 and 2

or cores 3 and 4 constitutes an output voltage from the amplifier.

On the basis of the statements in the preceding paragraph, the following equations are written

output = F_1 (input ampere-turns + Δ leakage current ampere-turns) (34)

Δ leakage current ampere-turns = F_2(output) (35)

Therefore

output = F_1, input + F_2 (output) (36)

This equation is of the form which commonly describes feedback systems.[5] Therefore it may be said that the change in shunt voltage as a function of output is a form of feedback.

Looking at the equation for the difference in shunt voltage in circuit 1, it is seen that V_{sh1} is larger than V_{sh2} for a positive signal with respect to the dot applied to the control winding. An increase in the shunt voltage V_{sh1} will tend to urge the cores 1 and 4 farther away from saturation. This is contrary to the effect of the control signal, which tends to urge the cores toward saturation. From this it may be deduced that the effect is that of negative feedback.

An examination of circuit 2 shows that for the same control circuit conditions V_{sh1} is larger than V_{sh2} for the half-cycle during which cores 3 and 4 are being reset. On the next half-cycle V_{sh2} will be larger than V_{sh1}. A quantitative measurement of the voltage across the shunts in circuit 2 would indicate that there is no difference in the shunt voltages. However, an examination of the wave form shows that the voltage is different on alternate half-cycles, as shown in Fig. 3(D) and (F). If V_{sh1} is larger than V_{sh2} during the interval that cores 3 and 4 are being reset, the change in leakage current will tend to urge the core farther away from saturation. This opposes the effect of the control signal and is therefore considered to be negative feedback.

In the next half-cycle, V_{sh1} is larger than V_{sh2}. In circuit 2 the leakage current through R_{sh2} is the bias current for core 1. The effect is the same as for the previous half-cycle, and is also considered to be negative feedback.

The difference in shunt voltages in circuit 1 may be divided into two parts

$$\bar{V}_{sh1}-\bar{V}_{sh2}=I_L(2R_w+4R_d)+\bar{V}_L\left(2+\frac{R_w+2R_d}{R_D}\right) \quad (37)$$

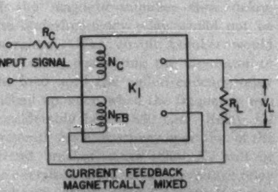

Fig. 5. Block diagram of amplifier with current feedback, magnetically mixed

From this equation it is seen that both load current and load voltage are factors in determining the feedback in the amplifier. Although the two are dependent upon each other, they are separate factors in the difference equation.

The difference in shunt voltages in circuit 2 may be arranged in a similar manner

$$\bar{V}_{sh1}-\bar{V}_{sh2}=I_L\left(2R_w+R_w\frac{R_L}{R_D}\right)=2R_wI_L+\frac{R_w}{R_D}\bar{V}_L \quad (38)$$

In this case, the feedback is a result of the impedance R_w and can be minimized by decreasing the winding resistance and the source impedance of the power supply.

In both circuits, there is feedback of voltage as a current and of current as a current. Fig. 4(B) shows the change in gain of a stage in circuits 1 and 2.

The feedback effect due to diode shunting can be related to the conventional feedback equations. This is equivalent to feedback into a separate winding, in the same winding configuration as the control winding. This type of circuit is shown in Fig. 5.[6] The gain expressions are, for open loop gain

$$K_I=\frac{I_L}{I_n}=\frac{I_L}{I_s}$$

I_s is the input signal and I_n is the net control current to which the amplifier responds.

Closed loop current gain is

$$K_I'=\frac{I_L}{I_s} \quad I_n=I_s-\frac{N_{fb}}{N_c}I_L$$

$$K_I'=\frac{I_L}{I_n+\frac{N_{fb}}{N_c}I_L}=\frac{K_I}{1+\frac{N_{fb}}{N_c}K_I} \quad (39)$$

Open loop voltage gain

$$K_e=K_I\frac{R_L}{R_s+R_c}$$

Closed loop voltage gain

$$K_e'=\frac{K_e}{1+\frac{N_{fb}}{N_c}\frac{R_s+R_c}{R_L}K_e} \quad (40)$$

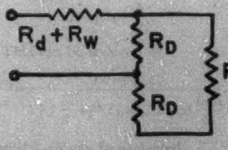

Fig. 6. Analysis of output network of amplifier with regard to maximum power transfer

In applying these equations to the shunt feedback effect, the gate winding is the counterpart of the feedback winding. The change in shunt voltage divided by shunt resistance is analogous to the feedback current.

Making these substitutions gives

$$K_I'=\frac{I_L}{I_n+\dfrac{N_g}{N_c}\dfrac{\Delta V_{sh}}{R_{sh}}} \qquad (41)$$

The differential change in shunt voltage is assumed to be equally divided

$$\Delta V_{sh}=\frac{1}{2}(V_{sh1}-V_{sh2}) \qquad (42)$$

Therefore for circuit 1

$$\Delta V_{sh}=\frac{I_L}{2}\left[\frac{2R_D+R_L}{R_D}(R_w+2R_d)+2R_L\right. \qquad (43)$$

$$K_I'=\frac{K_I}{1+\left(\dfrac{N_g}{N_c}\right)\left(\dfrac{1}{2R_{sh}}\right)\times\left[\dfrac{2R_D+R_L}{R_D}(R_w+2R_d)+2R_L\right]K_I} \qquad (44)$$

$$\beta=\left(\frac{N_g}{N_c}\right)\left(\frac{1}{2R_{sh}}\right)\times\left[\frac{2R_D+R_L}{R_D}(R_w+2R_d)+2R_L\right] \qquad (45)$$

For circuit 2

$$\Delta V_{sh}=\frac{I_L}{2}\left(\frac{2R_D+R_L}{R_D}\right)R_w \qquad (46)$$

$$K_I'=\frac{K_I}{1+\left(\dfrac{N_g}{N_c}\right)\left(\dfrac{1}{2R_{sh}}\right)\left(\dfrac{2R_D+R_L}{R_D}\right)R_wK_I} \qquad (47)$$

$$\beta=\frac{1}{2}\frac{N_g}{N_c}\frac{R_w}{R_{sh}}\left(\frac{2R_D+R_L}{R_D}\right) \qquad (48)$$

An analysis of the output network of the amplifier with regard to maximum power transfer yields the following equations

$$R_w+R_d=\frac{R_D+R_L}{2R_D+R_L}R_D$$

$$R_L=\frac{(R_w+R_d)R_D}{R_D+R_d+R_w}+R_D$$

See also Fig. 6.

Solving for R_D and R_L in terms of R_w and R_d gives

$$R_D=\sqrt{2}(R_w+R_d) \quad R_L=2(R_w+R_d)$$

Substituting these values in equations 45 and 48 gives for circuit 1

$$\beta=\left(\frac{N_g}{N_c}\right)\left(\frac{1}{R_{sh}}\right)\left[\left(3+\frac{1}{\sqrt{2}}\right)\times R_w+(4+\sqrt{2})R_d\right] \qquad (49)$$

and for circuit 2

$$\beta=\left(\frac{N_g}{N_c}\right)\left(\frac{R_w}{R_{sh}}\right)\left(1+\frac{1}{\sqrt{2}}\right) \qquad (50)$$

Graphic Analysis

The effect of the control signal on the shunt voltage is shown in Fig. 3.

For zero signal conditions, the shunt voltage in circuit 1 is equal to the shunt voltage in circuit 2. This is shown in Fig. 3(A) and (B). The sharp rise in the wave form occurs at the time the cores become saturated. Saturation occurs at approximately 70 degrees in this particular design.

Fig. 3(C) shows the increase in the voltage across R_{sh1} in circuit 1 when a signal voltage is applied which is positive with respect to the dot on the control winding. Fig. 3(E) shows the decrease in voltage across R_{sh2} for the same conditions.

Fig. 3(D) shows the increase in voltage across R_{sh1} in circuit 3, for a positive input voltage with respect to the dot of the control winding. On the following half-cycle the voltage decreases across the shunt. Examination of Fig. 3(F) indicates that this wave form is identical in form to that of Fig. 3(D) and out of phase with it by 1/2 cycle.

Conclusions

The gain of the full-wave, push-pull magnetic amplifier is related to the saturation level to which the saturable reactor is biased. The design equation for determining the value of shunt resistor to use in obtaining a particular saturation angle

$$R_{sh}=\frac{E(1+\cos\theta)}{\dfrac{H_\theta lm}{0.4\pi N_g}}\left(\frac{R_D+R_d+R_{wn}}{R_D+R_d+R_w}\right)$$

The shunt resistors create a feedback loop which introduces an appreciable amount of negative feedback into the amplifier. In instances where it is desirable to minimize the negative feedback, circuit 2 is more appropriate than circuit 1. In circuit 2, the feedback effect is a function of the winding resistance of the gate winding and the internal impedance of the power supply. It can be minimized to afford higher open-loop gain.

The feedback factor B, relating the feedback effect of the shunts on the open-loop gain of the amplifier, has been derived. Use of this factor is an aid in the analysis of the transfer function of this type of amplifier.

Inverse-Time Underfrequency Relay

R. G. HOFT
ASSOCIATE MEMBER AIEE

THIS PAPER describes a magnetic inverse-time underfrequency relay unit. It contains a relay which is operated when the frequency of an aircraft alternator drops below 380 cps (cycles per second). The time required for the relay to pick up is an inverse function of how far the frequency is below 380 cps. The complete unit contains a frequency-sensitive circuit which provides a voltage signal proportional to alternator frequency for driving a magnetic amplifier which has a very long time constant. The output of the magnetic amplifier is the coil of the underfrequency relay.

The unit is designed to operate over a wide temperature range, from −55 C (degrees centigrade) to +71 C, and a wide voltage range, from 70 to 115 volts. Furthermore it meets military specifications for aircraft equipment. Figs. 1 and 2 show a complete unit.

Circuit Operation

The elementary diagram of the relay unit is shown in Fig. 3. The input transformer *T1* provides power input from a 115-volt 400-cps single-phase source. The 100-volt secondary is connected to the frequency-sensitive circuit consisting of inductor *L1* and capacitor *C1*. The output of the frequency-sensitive circuit is the voltage across resistor *R6*. The circuit is such that this voltage decreases with increasing frequency in the range of from 220 to 400 cps.

The voltage across resistor *R6* is rectified and filtered so that it appears as a relatively smooth d-c output across resistor *R1*. This voltage is then compared with a bias voltage across resistor *R2*. The bias voltage is the rectified and filtered output of the 20-volt transformer secondary. Resistor *R3* is provided to permit slightly greater than the voltage across resistor *R1*. This slight difference of voltage, when applied to the F_2 magnetic-amplifier control winding in series with resistor *R4*, will produce just enough ampere-turns to bias the amplifier off.

When the frequency of the a-c input drops below 380 cps, the voltage across resistor *R1* will rise, turning on the magnetic amplifier which picks up relay *K1*. Control winding F_1 is provided to reduce the rate of flux change in the magnetic-amplifier cores, and thus increase the time constant of the amplifier. The time required for the relay to pick up is a direct function of the voltage applied to control winding F_2. If the frequency drops considerably below 380 cps, a large voltage will be applied to winding F_2 in series with *R4* to turn on the amplistat quickly. When the input frequency is just slightly below 380 cps, only a small voltage will be applied to control winding F_2, and it will take a relatively long time for the magnetic amplifier to turn on.

Control winding F_3 provides positive feedback to give the magnetic amplifier a snap characteristic; it is either fully off or almost fully on. This snap action reduces the effect of variations in the pickup point of the relay, and increases the sensitivity of the circuit; a smaller change in frequency will turn the magnetic amplifier from off to on.

Relay *K2* is provided to prevent false operation during startup of the alternator. With reference to Fig. 3, the undervoltage relay *UV* must be energized, and the underfrequency relay *K1* must be de-energized in order to pick up the circuit breaker which connects the alternator to the load. Without relay *K2*, if the rate of rise in alternator voltage were much greater than the alternator acceleration during a startup, the undervoltage relay would pick up while the underfrequency relay remained out of operation. Because of the magnetic-amplifier time delay, the underfrequency relay would not be energized. The circuit breaker would then close, connecting the alternator to the load until the underfrequency relay picked up, even when the frequency was considerably below 380 cps. Relay *K2* prevents this momentary operation of the circuit breaker, since relay *K2* will be de-energized until the undervoltage relay picks up. While relay *K2* is out of operation, a large voltage from the frequency-sensitive circuit will be applied to control winding F_2. This voltage will cause relay *K1* to pick up quickly. Therefore, the underfrequency relay will always be picked up before relay *UV* is energized, so that the circuit breaker will not be operated until the frequency is correct permitting relay *K1* to drop out.

Nomenclature

E = average voltage, volts
E_C = average control voltage, volts
E_S = average supply voltage, volts
e = instantaneus voltage, volts
e_C = instantaneous control current voltage, volts
H_e = dynamic loop coercive force of core material
I_C = average control current, amperes
I_e = average core-exciting current, amperes
l_{fe} = length of magnetic oersteds circuit, centimeters
N_C = numbers of turns on control windings
R_C = control circuit resistance, ohms
T = period of supply frequency, seconds
T_d = time delay, seconds
t = time, seconds
Φ_M = maximum flux (crest value) produced by alternating supply voltage, maxwells
Φ_S = saturation flux, maxwells
φ = core flux, maxwells
τ_d = time delay, cycles

Circuit Design

FREQUENCY-SENSITIVE CIRCUIT

The objective in the design of this circuit was to obtain as much change in voltage output as possible for a given change in frequency. Several circuits were investigated, but the one shown in Fig. 3 was the most satisfactory. Resistor-capacitor circuits and saturable-reactor circuits did not provide as much voltage-output variation for a given frequency change as did this resonant circuit.

The basic portion of the frequency-sensitive circuit is shown in Fig. 4. The approximate transfer function of this network may be determined as follows:

$$\frac{E_{out}}{E_{in}}=\frac{\dfrac{R\left(pL_2+\dfrac{1}{pC}\right)}{R+pL_2+\dfrac{1}{pC}}}{pL_1+\dfrac{R\left(pL_2+\dfrac{1}{pC}\right)}{R+pL_2+\dfrac{1}{pC}}} \qquad (1)$$

This can be reduced to

$$\frac{E_{out}}{E_{in}}=\frac{(1+p^2L_2C)}{1+p\dfrac{L_1}{R}+p^2(L_1+L_2)C+p^3\dfrac{L_1L_2}{R}C} \qquad (2)$$

and if L_1/R can be neglected

$$\frac{E_{out}}{E_{in}}\approx\frac{(1+p^2L_2C)}{1+p^2(L_1+L_2)C} \qquad (3)$$

Paper 56-738, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 26, 1956; made available for printing May 4, 1956.

R. G. HOFT is with the General Electric Company, Schenectady, N. Y.

The basic circuit for the relay unit was proposed by H. H. Britten and D. L. Plette of the General Electric Company.

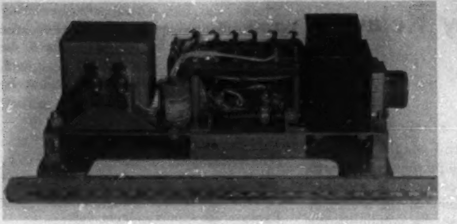

Fig. 1 (left). Inverse-time underfrequency relay, side view with cover removed

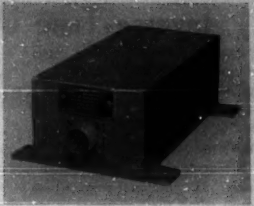

Fig. 2 (right). Inverse-time underfrequency relay unit, end view

This has an approximate frequency-response curve as shown in Fig. 5. Thus, in the range of from ω_1 to ω_2, the gain of the network will decrease as the frequency increases.

The gain of this network was calculated as a function of frequency by solving equation 3 using the following circuit constants:

L_1 = 0.635 henry
L_2 = 0.284 henry
C = 0.437 microfarad
R = 707 ohms

These values make ω_1 occur at approximately 1,580 radians per second, or 250 cps, and ω_2 at 2,840 radians per second, or 450 cps. The calculated curve is shown in Fig. 6. It is fairly linear over the range for the underfrequency relay.

The actual values of inductance, capacitance, and resistance selected were somewhat different from those indicated in the foregoing, so that it was possible to use a standard capacitor size. For the actual values shown in Fig. 3

$$\omega_1=\frac{1}{(L_1+L_2)C}=\frac{1}{0.8\times 0.5\times 10^{-6}}=1,580 \text{ radians per second, or 250 cps}$$

$$\omega_2=\frac{1}{L_2C}=\frac{1}{0.25\times 0.5\times 10^{-6}}=2,910 \text{ radians per second, or 460 cps}$$

The value of resistor *R6* is not critical, and, in fact, it can be eliminated without appreciably changing the output-voltage-versus-frequency curve from 220 to 380 cps. However, it was included in order to provide enough damping in the circuit so that the voltage applied to rectifiers *CR1* through *CR4* would not become too high at the resonant frequencies. The maximum rms voltage applied to these rectifiers was approximately 100 volts,

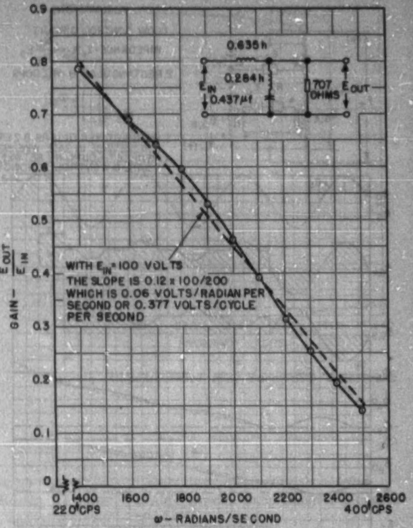

Fig. 6. Calculated gain versus frequency curve

with resistor *R6* equal to 800 ohms.

The filter capacitors *C2* and *C3* were extremely important. With the magnetic-amplifier supply voltage disconnected, the frequency-sensitive circuit would operate fairly well without these filter capacitors. The gain of the circuit was reduced somewhat because of ripple and the phase shift of the output voltages across the two bridge rectifiers, but otherwise the circuit operated properly. When the supply voltage was turned on, a change in frequency would not produce nearly as much effect on the magnetic-amplifier output as was expected. This was found to be caused by the induced current in control winding F_2 added to the ripple in the frequency-sensitive circuit rectifier outputs. The filtering is such that the frequency-sensitive circuit has approximately the effect on the amplifier that it should have based on the magnetic amplifier and the frequency-sensitive circuit gains separately operated.

MAGNETIC AMPLIFIER CIRCUIT

The magnetic amplifier used is a conventional, single-phase bridge-type amplifier. The supply voltage was determined by the requirements of relay *K1*. At the minimum input voltage to the relay unit of 70 volts, the magnetic-amplifier output current must be sufficient to pick up the relay. At the maximum input voltage of 115 volts, the maximum output current must not damage the relay. Both of these requirements were satisfied by a maximum magnetic-amplifier current output of approximately 60 ma (milliamperes) average and a maximum supply voltage to the magnetic amplifier of 70 volts. The maximum pickup current for relay *K1* is 20 ma and the largest permissible continuous coil current is 60 ma.

The magnetic amplifier was designed considerably underexcited; i.e., the normal supply of 70 volts at 380 cps produces a core flux amplitude Φ_M of approximately 20 per cent of Φ_S, provided that the cores are not driven into saturation. Arnold Engineering Company Deltamax cores are used with a saturation flux density B_S of 90,000 lines per square inch. The actual amplitude of the flux density for a supply of 70 volts and 380 cps is 18,400 lines per square inch for the cores which are used.

This underexcitation produces the required inverse-time characteristic, relatively independently of supply-voltage variation. When a step change in the d-c control voltage is applied to an underexcited magnetic amplifier which is biased off initially, it takes a period of time before the amplifier cores will saturate. The time before the cores saturate is a function of the instantaneous flux level when the step is applied, and of the magnitude of the step voltage. The steady-state change in flux level is produced by the d-c volt-seconds applied to the control circuit.

The response of an underexcited single-phase bridge magnetic amplifier to a step change in control voltage is shown in Fig. 7. The magnitude of the control-voltage step in this illustration was arbitrarily selected to be equal to $2N_C/N_G E_S$. Thus, the d-c control voltage referred to the gate circuits is $4/\pi$ times the peak value of the supply voltage. The d-c control volt-seconds are then equal to twice the a-c supply volt-seconds on each half-cycle.

It was assumed that the magnetic amplifier was off prior to the application of the step, and that the core fluxes were just reaching negative saturation on alternate half-cycles. This would be realized physically by having a slight but sufficient negative bias on the amplifier to drive the core fluxes slightly into negative saturation on alternate half-cycles. The core flux swings in the positive direction are produced by the alternating voltage applied to the gate circuits, and the negative flux swings are produced by the alternating voltage induced in the control-winding circuit. Prior to the application of the step of

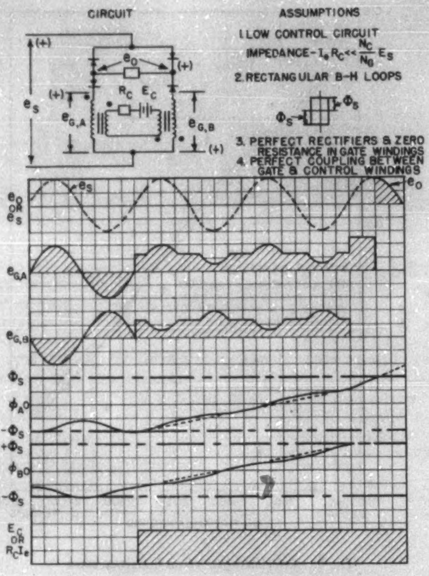

Fig. 7. Response to step change in control voltage

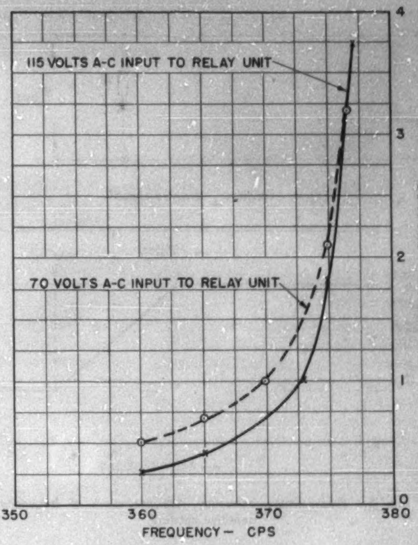

Fig. 8. Time–frequency curve

d-c control voltage, the control voltage is

$$E_C = R_C I_C = R_C I_e = R_C \frac{H_c l_{fe}}{0.4\pi N_C} \tag{4}$$

However this is very small, and has been neglected on the control-voltage curve in Fig. 7.

The wave shapes in Fig. 7 show how the core fluxes swing gradually toward positive saturation on consecutive half-cycles after the control-voltage step has been applied. During the first part of each half-cycle, one half of the d-c control voltage appears on each core. This control voltage reflected into the gate circuit is the only gate voltage on each core during this period. The rectifier cannot conduct in the gate circuit which is receiving a positive alternating voltage until the a-c gate voltage exceeds the reflected d-c control voltage. When this occurs, the a-c supply voltage becomes the gate voltage on the core whose rectifier is conducting. The gate voltage on the second core is the reflected total d-c control E_C minus the reflected alternating voltage induced in the control circuit from the conducting core. At the end of each half-cycle when the alternating voltage in the conducting gate drops below one half of the reflected d-c control voltage, again the gate voltages are each one half of the d-c control voltage.

During each complete cycle, the fluxes in each core move toward positive saturation by an amount equal to one half of the d-c control volts-seconds for a complete cycle. The net a-c flux swing in either core over a complete cycle is zero. Therefore, the magnitude of the d-c control-voltage step determines the time required for the core fluxes to reach positive saturation after the step has been applied. Since no magnetic-amplifier output can result until the cores saturate, there is a definite delay between the instant that a positive control-voltage step is applied and an output voltage is produced. (See Fig. 7.) This delay can be determined analytically as follows. In general

$$\frac{d\varphi}{dt} = \frac{e_C 10^8}{N_C} \tag{5}$$

Since there are two cores, the differential change in core flux in core A or core B, caused by the d-c control voltage E_C, when resistance drops are neglected, is

$$d\varphi_A = d\varphi_C = \frac{E_C 10^8}{2N_C} dt \tag{6}$$

The change in core flux on each cycle is exactly equivalent to having one half of the d-c control voltage on each core for the complete cycle, as shown in Fig. 7. Thus

$$\Delta\varphi_A/\text{cycle} = \Delta\varphi_B/\text{cycle} = \frac{E_C 10^8}{2N_C} T \tag{7}$$

Now, prior to the application of the step change in control voltage, the core fluxes alternate about a flux level Φ_M above negative saturation. The total flux change $\Delta\varphi_T$ required before the cores can reach saturation, the alternating component of the fluxes being neglected, is then

$$\Delta\varphi_T = 2\Phi_S - \Phi_M \tag{8}$$

If T_d is the time delay between when the step change in control voltage occurs and when the magnetic amplifier is fully on, the time delay, in cycles, of the magnetic-amplifier supply frequency is

$$\tau_d \approx \frac{2\Phi_S - \Phi_M}{\frac{E_C 10^8}{2N_C} T} \tag{9}$$

or, in seconds

$$T_d \approx \frac{2N_C}{E_C 10^8}(2\Phi_S - \Phi_M) \tag{10}$$

and therefore T_d is inversely proportional to the d-c control voltage.

For the conditions shown in Fig. 7, the time delay is

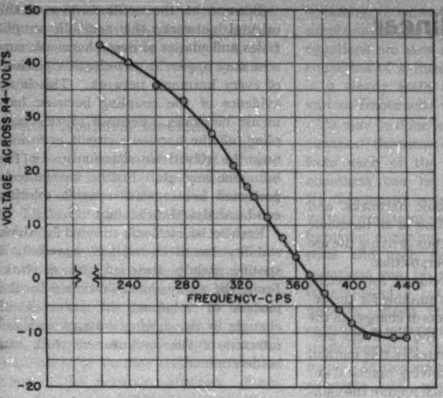

Fig. 9. Frequency-sensitive circuit characteristic

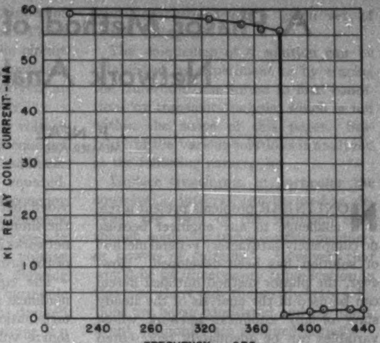

Fig. 10. Underfrequency relay steady-state characteristic

$$\tau_d \approx \frac{2\Phi_s - 10\% 2\Phi_s}{40\% 2\Phi_s/\text{cycle}} = 2.25 \text{ cycles} \qquad (11)$$

The expression for T_d in equation 9 or 10 is not exact because it does not consider when, in the cycle, the control-voltage step is applied, nor does it consider the time delay between when the cores first begin to saturate and when the magnetic amplifier is fully on. However, if the time delay is considerably greater than the period of the supply frequency, and if the amplifier goes from partially on to fully on in a few cycles, equation 9 or 10 will be an accurate measure of the magnetic-amplifier time delay.

It will be noted from the wave shapes in Fig. 7 that if the a-c flux swing is much less than $2\Phi_s$, the time delay will be relatively independent of alternating voltage. The effect of the control winding shunted by resistor *R5* (Fig. 3) is to increase the time delay. This may be considered as essentially placing a shunting resistor across control winding F_2, which reduces the control voltage by the ratio of this reflected resistance to resistor *R4* plus the reflected resistance.

Test Data

Figs. 8, 9, and 10 show test data for a sample unit. The test procedure for obtaining this data is explained in the Appendix. Fig. 8 is a plot of the measured time-frequency curve for the relay unit. Each point on this curve shows the time delay before the *K1* relay picked up after instantaneously dropping the input frequency from 380 cps to the frequency for the particular point on the curve. With 115 a-c input volts the *K1* relay dropped out at 386 cps, and with 70 a-c input volts the relay dropped out at 387 cps. Fig. 9 shows an output voltage versus frequency curve for the frequency-sensitive portion of the circuit; Fig. 10 is a plot of the *K1* relay current versus input frequency to the relay unit.

Conclusions

This magnetic-amplifier inverse-time underfrequency relay is a simple and reliable unit for indicating underfrequency on an a-c bus. Relatively long time delays are possible with the underexcited magnetic-amplifier circuit. This circuit combined with the frequency-sensitive circuit provides a fairly accurate inverse-time characteristic. Although no temperature tests were conducted, resistors with low-temperature coefficients and a special, mineral-oil-filled 0.5-microfarad capacitor were used, so that the circuit should not be appreciably affected by temperature variations.

Appendix. Test Procedure

The underfrequency relay unit is somewhat difficult to test with standard generating equipment. It is necessary to change the frequency of the a-c supply very quickly, and this is difficult with a motor-generator set. One method, however, is to use an electronic oscillator and an audio-amplifier as the a-c power supply. This was used in the General Electric Company laboratory, to test the development samples of the relay unit and adjust them for proper operation.

The following test equipment was required:

1 Kron-Hite oscillator model no. *440-A*

1 Altec Lansing audio amplifier catalogue no. *A256C*

1 Berkeley counter model no. *5500E*

The test procedure listed below was followed to test and adjust the relay units:

1. Connect the relay unit to the audio-amplier oscillator power supply.
2. Set the a-c input at 115 volts and 377 cps.
3. Adjust the bias resistor *R3* until the relay just picks up; this can be indicated by connecting an ohmmeter across terminals *A* and *C* on the unit.
4. Connect the Berkeley counter to record the time between when the oscillator frequency is changed and when the relay picks up. (This was done by connecting the starting input of the counter to a 1.5-volt battery through a push button. This button was pressed at the same time that the oscillator push buttons were pressed to change the input frequency. The "stop" input to the counter was connected to a battery in series with the normally open *K1* relay contacts.)
5. Press the oscillator buttons to change the input frequency and the auxiliary push button simultaneously, and record the time indicated on the counter.
6. Repeat this for several different frequency steps down from 380 cps.
7. If the time frequency curve is not as required, adjust *R5* to change the time delay, and repeat steps 5 and 6 until the desired curve is obtained.

A Phasor Method of Nonlinear Network Analysis

J. P. NEAL
MEMBER AIEE

NONLINEAR problems present a real challenge to any engineer because no completely satisfactory general method of solution has been developed. However, the phasor method outlined herein can be used in the analysis of the steady state of any nonlinear network whose variables can be adequately represented by the sum of a limited number of simple sinusoidal functions of time. The method is the result of an effort to digest some of the classical approaches to the solution of nonlinear problems so they can be applied by means of elementary mathematics and at the same time provide a grasp of the influence of the individual nonlinear elements on the steady state of the nonlinear networks. It has the object of providing a tool for nonlinear analysis and synthesis to engineers who have not had extensive training in that area.

The direct attack used in this method requires some engineering judgment for the determination of the frequencies which are significant in the analysis. However, in practical engineering problems, such as the one which is referred to in the illustration of this method, adequate engineering information is often obtainable from experiment and preliminary analysis of the possible resonant frequencies of the physical system represented by the particular nonlinear network involved.

It is well known that the principle of superposition does not apply to nonlinear systems. This is often stated as an objection to employing the principle of equivalent linearization in nonlinear solutions. However, the method of this paper does not treat each harmonic independently. Mutual coupling is provided between harmonic networks, and the simultaneous solution of all harmonic networks is required, thus denying the use of the principle of superposition.

The equations developed for specific nonlinear solutions are suitable for the determination of the effects of changes in the source voltages or in the nonlinear network parameters. Therefore, this method provides a means for solving practical engineering problems which require the elimination of undesirable effects or the creation of desirable effects caused by the network nonlinearities.

This paper is presented in terms of the mesh method with source functions which are regulated voltages, and nonlinear parameters which are functions of currents. However, where source functions are regulated currents and nonlinear parameters are functions of voltages, the node method may be similarly employed.

Summary of the Method

The phasor method of nonlinear network analysis may be summarized in the following manner. Consider an electrical nonlinear network where all sources are regulated voltages and can be represented by finite sums of simple sinusoidal functions of time. The frequencies significant to the performance of the network are initially selected on the basis of experience. Mesh currents are then established, in symbolic form, with harmonic components at the significant frequencies. By substituting the symbolic forms of the mesh currents and simplifying the resultant expressions by trigonometric identities, each element voltage is arranged as the sum of a finite series of simple sinusoidal functions of time.

A set of circuit equations for each significant harmonic frequency is finally obtained by the substitution of the corresponding frequency term of each element voltage for each appearance of that voltage in the circuit (voltage) equations of the nonlinear network. Now, a harmonic network can be defined for each significant frequency by the corresponding harmonic set of circuit equations. Also, the harmonic voltages and currents can be represented in phasor form.

Because of the nonlinearities of the original network, the symbolic amplitudes and phases of every harmonic current may appear in the circuit equations of every harmonic network. This is an evidence of the coupling between harmonic networks. Because of this coupling, all the harmonic circuit equations must be solved simultaneously for the harmonic currents. Finally, by the tests presented herein, each specific solution can be analyzed for stability.

Each set of harmonic currents for which stability has been verified represents a specific steady state of the network. From the expressions developed in the process of solution, the influence of changes in the driving voltages and parameters of the nonlinear network can be determined.

Comparison with Linear and Computer Methods

Network analysis may be described as the process of relating the network currents to the source voltages and the element parameters. It is most directly accomplished by solving the circuit equations for the network currents and then mathematically analyzing the influence of each source voltage and element parameter on the network currents.

For linear networks, the usual phasor method provides an efficient tool for steady-state analysis when the source voltages can be expressed by the sum of a limited number of simple sinusoidal functions of time. Then, the general solution of the steady state is reduced to the solution of a correspondingly limited number of sets of simultaneous linear algebraic equations in terms of phasors with complex number coefficients.

For any type of network, after the time and effort necessary to establish the computer program has been expended, individual numerical solutions and families of such solutions can be rapidly calculated by automatic computers. Furthermore, unique solutions to specific problems will be obtained because the currents are traced, step by step, from initial to final conditions. However, network performance can then be analyzed only on the basis of results, rather than by means of functional forms developed in the process of solution.

For many nonlinear networks, the method described herein provides a process for the construction of steady-state solutions by phasor methods quite similar to those normally used in linear network analysis. In fact, if applied to a linear network, it reduces to the usual

This paper is based, in part, on a thesis presented to the Graduate College in partial fulfillment of the requirements for the Ph. D. degree in electrical engineering at the University of Illinois, 1955. The research was conducted under the supervision of Dr. G. H. Fett. Work on the thesis was supported, in part, by the General Electric Company.

phasor method of linear network analysis. The method has its limitations but does provide an engineering approach to and clearer understanding of many nonlinear problems.

Related Nonlinear Methods

The original approach to the solution of nonlinear differential equations, the method of perturbations, was described by Lindstedt and Poincare and has been extended by Van der Pol and others.[1–3] Kryloff and Bogoliuboff have more recently developed a method of equivalent linearization which shows how linearized elements can be developed to replace nonlinear network elements.[4,5] In effect, their linearized parameters are the coefficients of Fourier series representations of the network activities. Johnson, Thomsen and Schlesinger and others have shown how similar concepts can be successfully employed in the analysis of simple nonlinear networks.[6,7,8] These concepts are extended in this paper to multimesh-multinode networks, and simplified stability tests are developed and presented.

The steady state of any network is progressively complicated as nonlinear elements are introduced. The majority of the published work on nonlinear network analysis is devoted to networks containing only one nonlinear element. A phasor method of analysis of a multimesh-multinode network containing a single nonlinear element is very little more complicated than that of a single mesh or node-pair nonlinear network since, at any given frequency, the linear portion of any network can be replaced by a Thevenin or Norton equivalent. Such cases include only those nonlinear networks whose phasor-form equations for a single harmonic can be algebraically simplified to a single nonlinear phasor-form harmonic equation. More complicated networks can be solved by the method proposed herein.

General Description of the Method

Consider a nonlinear network operating in a specific steady state wherein each of the voltages and currents can be adequately represented by a finite series of simple sinusoidal functions of time. When these series representations of the mesh currents and source voltages have been substituted into the circuit equations for the nonlinear network, the terms can be simplified by means of trigonometric identities to simple sinusoidal time functions. This provides a set of equations consisting of sums of a finite number of simple sinusoidal time functions. These equations are now similar to the circuit equations of a linear network operating in a steady state and being driven at various frequencies simultaneously.

As may be done with any linear voltage equation, the terms of the same frequency from each of the simplified nonlinear equations can be separately equated. By this means, a set of single-frequency voltage equations can be derived for each harmonic occurring in the specific steady state and each derived set of voltage equations can be used as the defining equations of a corresponding harmonic network. Each term in each derived equation is interpreted as the voltage of a single linearized harmonic network element. In this manner, a set of harmonic networks are constructed which are equivalent, for that specific steady state, to the original nonlinear network.

The proposed phasor method of nonlinear network analysis follows the procedure just outlined except that the mesh currents and source voltages are represented in general form by finite trigonometric series having symbolic amplitudes and phase angles, and the specific harmonic frequencies found to be significant for the region of operation under investigation.

The selection of the significant harmonics is the crux of this method. It is based on previous experience, experiment, and preliminary analysis, with special attention to any resonant circuits in the harmonic networks. Very nonsinusoidal wave forms may often be represented by the sum of a very few harmonic components; if so, a few significant harmonics are often adequate for practical purposes.

In each simplified harmonic-circuit equation, the coefficient of each harmonic current is interpreted as the parameter of a linearized element in the corresponding harmonic network. At this point, since each simplified harmonic-circuit equation contains terms of a single frequency, the harmonic voltages, currents, and parameters may be represented by complex numbers and the balance of the analysis carried forward in phasor form.

Due to the nonlinearities of the original network, the parameters of the linearized harmonic elements can be functions of the amplitude and phase angle of any of the harmonic currents. Therefore evaluation of the amplitudes and phase angles of the harmonic currents requires the simultaneous solution of all of the circuit equations for each specific set of source voltages. This coupling which exists between the harmonic networks leads to multiple solutions for a given set of source voltages.

The uniqueness of a solution can be established by experiment or by tracing the transition from initial to final conditions by transient analysis, which is not within the scope of this paper. Stability of the various solutions is analyzed in the following paragraphs.

Laplace transforms, in particular the convolution integral, can be used to develop the form of the solutions even though nonlinear terms contain products or powers of currents.[9] However, that would be an unnecessary complication in this case where only the steady-state solutions are being considered and the significant harmonics are assumed initially.

STABILITY CONSIDERATIONS

For any specific solution to represent a steady state it must be stable. Instability may exist because random disturbances will not die with time or will cause a relatively gradual transition to a more stable state. Therefore, two types of stability tests are needed. The test which determines the instantaneous influence of small random disturbances is called the instant-stability test. The test which determines whether a relatively gradual transition to a more stable state will occur is called the average-stability test.

INSTANT-STABILITY TEST

The instant-stability test assumes that small random variations of each harmonic current encounter the same instantaneous influence as that encountered by that harmonic current in the linearized harmonic network. In other words, each harmonic network is examined for stability as though it were a linear network, each parameter being held constant at the value obtained for the specific solution under test.[5] For each set of harmonic-voltage equations in phasor form, p_h is substituted into the parameter determinant for $j\omega_h$ and the determinant is equated to zero and solved for the values of p_h. If the real component of any value of p_h is positive, the harmonic network is unstable for that specific solution and the solution does not represent a steady state. As with linear networks, instant stability can be verified directly from the determinantal equation in terms of p_h by application of the Routh-Hurwitz criterion.

AVERAGE-STABILITY TEST

The average-stability test assumes that, after instant stability has been verified, small random variations of the amplitudes and phase angles of the harmonic currents can be analyzed by the method of variations. The Poincare-Liapounoff criteria have been applied to the variational equations.[4] On that basis, the author developed certain tests as shown in the following. The derivation of the average-stability tests is outlined in Appendix I. The tests analyze the apparent input impedance facing each harmonic source, i.e., the complex number ratio of the harmonic source voltage to the harmonic input current. The average-stability conditions for each harmonic source and specific steady state are

$$\left[\frac{\partial(I^2R)}{\partial I}-\frac{\partial(IX)}{\partial\theta}\right]>0$$

$$\left\{\frac{\partial(IZ)^2}{\partial I}+2\left[\frac{\partial(IX)}{\partial I}\,\frac{\partial(IR)}{\partial\theta}-\frac{\partial(IR)}{\partial I}\,\frac{\partial(IX)}{\partial\theta}\right]\right\}>0$$

where

$Ee^{j\theta}$ = harmonic source voltage
$Ie^{j\theta}$ = harmonic input current
$Ze^{j\theta}$ = harmonic input impedance

and where R, X, and Z in the following equations are functions of I and θ

$$Z^2=R^2+X^2$$

$$P=I^2R$$

$$E=IZ$$

When the variations with respect to θ are negligible, the average-stability conditions reduce to

$$\frac{\partial P}{\partial I}>0 \text{ and } \frac{\partial E}{\partial I}>0$$

GRAPHIC EVIDENCE OF INSTABILITIES

At any harmonic source, zero or negative values of $\partial E/\partial I$, when linearized parameters are assumed constant, indicate instant instability.

If the variations with respect to θ are negligible, average stability is indicated at a particular harmonic source when the graphs of P and E versus I have positive slopes, providing instant stability has been verified.

Illustrative Application of the Method

A step-by-step illustrative application of this phasor method of nonlinear network analysis is presented in Appendix II. The network pertains to a practical problem which was proposed by the Ballast Department of the General Electric Company now located at Danville, Ill. That problem required the analysis of a peculiar instability which had caused undesirable oscillations of a frequency in the order of one cycle per second in an experimental fluorescent lamp and ballast system. The illustrative problem has previously been discussed.[11]

The analysis of the experimental system pertaining to the example shows that the illustrative network approached instant instability for higher source voltages because certain harmonic parameter-coefficients (r_{m2} and l_{m2}) became negative. Some discrepancy between measured and calculated results is possible because the nonlinear network of the example is not an exact mathematical model of the physical system to which it is said to be equivalent.

Conclusions

The method presented for analyzing multimesh-multinode nonlinear networks has a number of worth-while features. When the steady-state activities of a basic nonlinear network can be represented by the sum of a finite number of simple sinusoidal functions of time, the basic nonlinear network is suitable for this method. The prediction of the activities of that network can then be evaluated to any desired degree of accuracy if sufficient labor is expended.

The amount of labor required should not be overestimated. For repetitious calculations with similar networks the lengthy expansions need not be repeated. Identities relating polynomials of variables which are sums of simple sinusoidal functions of time to the expansions of those polynomials in terms of sums of simple sinusoidal functions of time, such those as listed in Appendix II, can be prepared or may be available. Then, the labor required for the evaluation of a specific steady-state solution may be comparable to that required for the evaluation of the steady-state solution of a linear network of similar plan and with the same number of harmonics present.

The crux of the method is the choice of the significant harmonics, since the reliability of the answers obtained is dependent on the correctness of the selection of the significant harmonics. As with many engineering problems, many false starts can be avoided if some concept of the form of the answer is known. The selection can be based on previous analyses of similar systems, preliminary analyses, or experiment.

Existence theorems for the solutions obtained by the method of equivalent linearization are given by Kryloff and Bogoliuboff in a series of papers, two of which have been translated and incorporated in a monograph by Lefschetz.[5] These theorems provide a basis for the method of approximate solutions which is a feature of the phasor method of nonlinear network analysis described herein.

The procedures used in this method are so similar to those used in linear network analysis that they may be followed without extensive additional training. The mathematics involved are primarily algebra, trigonometry, and the use of the phasor method of representing and manipulating simple sinusoidal functions of time.

The complete nonlinear influences are divided into component influences which can be successfully analyzed and evaluated. The linearized harmonic networks allow each harmonic to be analyzed somewhat independently as though the principle of superposition applied. Coupling between the linearized harmonic networks takes into account the conditions which prevented the use of the principle of superposition.

Appendix I. Development of Tests for Average Stability

The tests for the instant stability of the linearized harmonic networks assume that the linearized harmonic element parameters can be considered as constant over infinitesimal intervals. This is a reasonable assumption for instantaneous variations. However, the variations of the linearized parameters over finite intervals may not be negligible. The linearized parameter values are average functions of the harmonic current values, and therefore a test weighing the influence of changes in these parameter values is logically called an average-stability test.

The average-stability tests developed here apply separately to each linearized harmonic circuit and neglect any secondary influences due to coupling with other harmonic circuits or networks. That is, each harmonic circuit is considered as having linearized R, L, and C elements which are functions only of the current circulating throughout that harmonic circuit and influences from other harmonic circuits and networks are grouped together as a harmonic source voltage. On this basis, any harmonic circuit equation can be arranged as

$$L\ddot{q}+R\dot{q}+Sq=e$$

where q and e are periodic functions of time at the harmonic frequency ω, to which the circuit pertains. R, L, and S represent resistance, inductance, and elastance respectively, the linearized circuit parameters. The linearized circuit parameters may be functions of the amplitude Q and the phase θ of the harmonic charge q. Let

$$e=E\sin(\omega t+\theta)$$

$$q=Q\cos\omega t$$

$$\dot{q}=-\omega Q\sin\omega t$$

$$\ddot{q}=-\omega^2Q\cos\omega t$$

$$\theta=\tan^{-1}[\omega R/(\omega^2L-S)]$$

As a first step in this development, the inhomogeneous harmonic circuit equation will be rearranged in homogeneous form by transposing all terms to the left side of the equation. The equation is then in the form $L\ddot{q}+R_e\dot{q}+S_eq=0$, where

$$R_e=R+(E/\omega Q)\cos\theta$$

$$S_e=S-(E/Q)\sin\theta$$

The only case considered hereafter is where $R_e<4LS_e$. Then $q=Q\epsilon^{-\delta_p t}\cos\omega_p t$, where

$$\delta_p=(R_e/2L)$$

$$\omega_p=\sqrt{(S_e/L)-(R_e^2/4L_e^2)}$$

$$\theta=(\omega-\omega_p)t$$

For small variations of amplitude or phase, assume that

$$\dot{Q}=-\delta_pQ$$

$$\dot{\theta}=\omega-\omega_p$$

$$I=-\omega Q$$

$$\dot{I}=-\delta_pI$$

Thus

$$\dot{I}=-(R_e/2L)I=-(RI-E\cos\theta)/2L$$

$$\dot{\theta}=\omega-\{SL+(\omega LE/I)\sin\theta-[R-(E/I)\cos\theta]^2\}^{1/2}/L$$

Now, apply the method of variations as shown by Minorsky.[4] Let

$$I=I+\beta$$

$$\theta=\theta+\varphi$$

then

$$\dot{I}=\dot{\beta}$$

$$\dot{\theta}=\dot{\varphi}$$

The expansion of $\dot{I}$ and $\dot{\theta}$ in Taylor series about $I=I$ and $\theta=\theta$ gives

$$\dot{\beta}=\left(\dot{I}+\beta\frac{\partial\dot{I}}{\partial I}+\varphi\frac{\partial\dot{I}}{\partial\theta}+\ldots\right)$$

$$\dot{\varphi}=\left(\dot{\theta}+\beta\frac{\partial\dot{\theta}}{\partial I}+\varphi\frac{\partial\dot{\theta}}{\partial\theta}+\ldots\right)$$

Neglecting the implied higher-order terms and solving the equations simultaneously results in

$$\ddot{\varphi}-\left(\frac{\partial\dot{I}}{\partial I}+\frac{\partial\dot{\theta}}{\partial\theta}\right)\dot{\varphi}+\left(\frac{\partial\dot{I}}{\partial I}\frac{\partial\dot{\theta}}{\partial\theta}-\frac{\partial\dot{I}}{\partial\theta}\frac{\partial\dot{\theta}}{\partial I}\right)\varphi=\dot{I}\frac{\partial\dot{\theta}}{\partial I}$$

$$\ddot{\beta}-\left(\frac{\partial\dot{I}}{\partial I}+\frac{\partial\dot{\theta}}{\partial\theta}\right)\dot{\beta}+\left(\frac{\partial\dot{I}}{\partial I}\frac{\partial\dot{\theta}}{\partial\theta}-\frac{\partial\dot{I}}{\partial\theta}\frac{\partial\dot{\theta}}{\partial I}\right)\beta=\dot{\theta}\frac{\partial\dot{I}}{\partial\theta}$$

Considering the homogeneous form of the preceding equations, i.e., neglecting the right-hand terms, variations β and φ decrease with time and the periodic activity continues when

$$\left(\frac{\partial\dot{I}}{\partial I}+\frac{\partial\dot{\theta}}{\partial\theta}\right)<0$$

$$\left(\frac{\partial\dot{I}}{\partial I}\frac{\partial\dot{\theta}}{\partial\theta}-\frac{\partial\dot{I}}{\partial\theta}\frac{\partial\dot{\theta}}{\partial I}\right)>0$$

Partially differentiating $\dot{I}$ and $\dot{\theta}$ as necessary, and then setting

$$R_e=0$$

$$E\cos\theta=RI$$

$$E\sin\theta=\left(\omega L-\frac{S}{\omega}\right)I=XI$$

$$Z^2=R^2+X^2$$

gives

$$\frac{\partial\dot{I}}{\partial I}=-\frac{R}{2L}-\frac{I}{2L}\frac{\partial R}{\partial I}=-\frac{1}{2LI}\left[\frac{\partial(I^2R)}{\partial I}-IR\right]$$

$$\frac{\partial\dot{I}}{\partial\theta}=-\left(\frac{XI}{2L}+\frac{I}{2L}\frac{\partial R}{\partial\theta}\right)=-\frac{1}{2LI}\times\left[I^2X+I\frac{\partial(IR)}{\partial\theta}\right]$$

$$\frac{\partial\dot{\theta}}{\partial I}=\frac{1}{2LI}\left(X+I\frac{\partial X}{\partial I}\right)=-\frac{1}{2LI}-\left[\frac{\partial(IX)}{\partial I}\right]$$

$$\frac{\partial\dot{\theta}}{\partial\theta}=-\frac{1}{2L}\left(R-\frac{\partial X}{\partial\theta}\right)=-\frac{1}{2LI}\times\left[-\frac{\partial(IX)}{\partial\theta}+IR\right]$$

By substitution of these expressions and subsequent simplification, the average-stability conditions for a linearized harmonic network can be expressed as

$$\left[\frac{\partial(I^2R)}{\partial I}-\frac{\partial(IX)}{\partial\theta}\right]>0$$

$$\left\{\frac{\partial(IZ)^2}{\partial I}+2\left[\frac{\partial(IX)}{\partial I}\frac{\partial(IR)}{\partial\theta}-\frac{\partial(IR)}{\partial I}\frac{\partial(IX)}{\partial\theta}\right]\right\}>0$$

When R, X, and Z are practically independent of θ the average-stability conditions simplify to

$$\frac{dP}{\partial I}>0 \quad \text{where } P=I^2R$$

$$\frac{\partial E}{\partial I}>0 \quad \text{where } E=IZ$$

Appendix II. Illustrative Application of the Method

The phasor method of nonlinear network analysis is illustrated, step-by-step, by reviewing its application to a practical network equivalent to an experimental fluorescent lamp and ballast system.

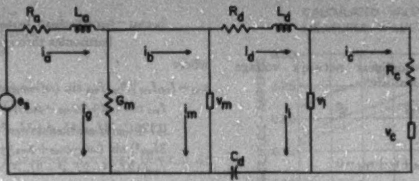

Fig. 1. Basic nonlinear example-network

Step 1. Specification of Basic Nonlinear Network

The plan of the basic nonlinear network of this example is illustrated in Fig. 1.

The element voltages of the basic nonlinear network are in volts

$$e_s=E_{s1}\sin(\omega t+\phi_{s1})$$

$$v_{Ra}=R_ai_a$$

$$v_{La}=L_a\dot{i}_a$$

$$v_{Rd}=R_di_d$$

$$v_{Ld}=L_d\dot{i}_d$$

$$v_{Gm}=R_mi_g$$

$$v_{Cd}=(1/C_d)q_d$$

$$v_{Rc}=R_ci_c$$

$$v_m=L_m\dot{i}_m$$

$$v_l=R_li_l+\sum_h A_{lh}\dot{i}_{lh}$$

$$v_c=(1/c)q_c$$

where

$\omega=377$ radians per second
$R_a=R_d=42$ ohms
$L_a=L_d=0.62$ henrys
$C_d=1.4\times10^{-6}$ farads
$G_m=(1/R_m)=65\times10^{-6}$ mhos
$R_c=1,250$ ohms
$c=(0.7\times10^{-6}/I_{l1})$ farads

$$L_m=(A_m+B_mi_m^2-C_mi_m^4)$$

where

$A_m=19$ henrys
$B_m=2\times10^4$ henrys per ampere^2
$C_m=15\times10^8$ henrys per ampere^4

$$R_l=A_l+B_li_l^2$$

where

$A_l=-(135/I_{l1})$ ohms
$B_l=(600/I_{l1}^3)$ volts per ampere^3
$A_{lh}=18,000/(h\omega I_{l1})^2$ henrys

The operating region of interest is $I_{a1}=0.22$ to 0.28 ampere. Subscripts relate to elements in Fig. 1. The positive reference of any v is at the tail of the associated current reference arrow, any e has the opposite reference.

The circuit currents of the basic nonlinear network are taken as i_g, i_m, i_l, and i_c. The other currents, in terms of the circuit currents, are

$$i_a=i_g+i_m+i_l+i_c$$

$$i_s = i_m + i_t + i_c$$

$$i_d = i_t + i_c$$

The basic nonlinear network voltage (circuit) equations are

$$v_{Rs} + v_{Ls} + v_m = e_s$$

$$-v_{Gm} + v_m = 0$$

$$-v_m + v_{Rd} + v_{Ld} + v_t + v_{Cd} = 0$$

$$-v_t + v_{Rc} + v_c = 0$$

Step 2. Selection of Significant Harmonics

Harmonic analyses and experiments with the system to which the example network is equivalent indicated four significant harmonics for the region of operation considered here: $h=0, 1, 2,$ and 3.

The general expression for each current is assumed as

$$i_k = I_{k0} + \sum_{h=1}^{3} i_{kh} = I_{k0} + \sum_{h=1}^{3} I_{kh} \sin \alpha_{kh}$$

$$= I_{k0} + \sum_{h=1}^{3} I_{kh} \sin (h\omega t + \phi_{kh})$$

where k identifies the associated element.

Furthermore, for any specific steady state

$$q_k = \sum_{h=0}^{3} q_{kh} = Q_{k0} + \sum_{h=1}^{3} Q_{kh} \cos \alpha_{kh}$$

$$= Q_{k0} + \sum_{h=1}^{3} (-I_{kh}/h\omega) \cos \alpha_{kh}$$

$$\dot{i}_k = \sum_{h=1}^{3} \dot{i}_{kh} = \sum_{h=1}^{3} h\omega I_{kh} \cos \alpha_{kh}$$

Step 3. Expansion of Basic Nonlinear Element Voltages

For each basic nonlinear element, the trigonometric representations of the currents are substituted into the element voltage function and the resultant expression is simplified to a series of simple sinusoidal functions of time by the use of trigonometric identities.

This step produces terms of frequencies additional to those previously classed as significant. If the significant harmonics were properly selected these additional terms may be discarded, as they are in this example. If there is doubt about the adequacy of the significant harmonics, it may be desirable to retain the additional frequency terms and observe their influence in subsequent steps.

The expanded, simplified, and subdivided nonlinear element voltages of the example nonlinear network for the region considered are shown in the following. To conserve space, the simplified trigonometric expansions are subdivided in anticipation of steps 4, 5, and 6. For each harmonic of each element voltage the terms are grouped into a harmonic source voltage and harmonic linearized element voltages as explained in step 4. The nonlinear element voltages v_m, v_t, and v_c expressed as sums of simple sinusoidal functions of time are, as follows

$$v_m = -e_{m1} + r_{m1}i_{m1} + l_{m1}\dot{i}_{m1} - e_{m2} + r_{m2}i_{m2} + l_{m2}\dot{i}_{m2} - e_{m3} + r_{m3}i_{m3} + l_{m3}\dot{i}_{m3} + \text{higher harmonics through the 15th,}$$

where

$$e_{m1} = I_{m2}I_{m3}\{B_m[I_{m0} \sin (\omega t - \phi_{m2} - \phi_{m3}) - I_{m2} \cos (\omega t + 2\phi_{m2} - \phi_{m3})] + 0.125C_m[4I_{m0}(4I_{m0}^2 + 3I_{m2}^2 + 3I_{m3}^2) \sin (\omega t - \phi_{m2} + \phi_{m3}) + I_{m2}(12I_{m0}^2 - 2I_{m2}^2 + 3I_{m3}^2) \times \cos (\omega t + 2\phi_{m2} - \phi_{m3})]\}$$

$$l_{t3} = A_{t3}$$

$$v_c = (1/c)(q_{c0} + q_{c1} + q_{c2} + q_{c3})$$

Step 4. Specification of Harmonic

Each harmonic network has the same plan and element locations as the basic nonlinear network. The voltages of the linear harmonic elements are the same as those in the basic nonlinear network. The voltages of the linearized harmonic elements are the harmonic terms of the step 3 expansions for the corresponding basic nonlinear elements.

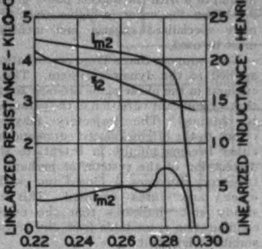

Fig. 2. Calculated and measured input currents and powers versus input voltage for the example network

Every basic nonlinear element is represented in a harmonic network by a series combination including a linearized harmonic source and linearized passive elements, depending upon the terms forming the element voltages. Terms which are not functions of the instantaneous harmonic current designate a linearized harmonic source. Terms which are functions of the instantaneous harmonic current designate a linearized resistance, inductance, or capacitance, according to the form of the terms.

For example, for the first harmonic network, v_{m1} includes all the first harmonic terms of v_m. Of the terms included in v_{m1}, those which include i_{m1}, $\dot{i}_{m1}$, or q_{m1} explicitly constitute linearized passive voltages, the other terms constitute a harmonic source voltage which is designated e_{m1}. The coefficients of i_{m1} constitute a linearized resistance. The coefficients of $\dot{i}_{m1}$ constitute a linearized inductance. Because q_{m1} does not appear in v_{m1}, there is no linearized capacitance in this instance.

Step 5. Development of Harmonic Phasors

As explained and demonstrated in the preceding steps, the voltage of each harmonic network element consists of a harmonic source voltage or of a linearized coefficient or parameter multiplying a current. Therefore, as with linear networks, each harmonic voltage and current can be represented, for a specific steady state, as a stationary phasor in complex or polar form for the particular harmonic frequency.

The phasor representations for the voltages and currents of the example, with the use of maximum-value phasors and the parameters listed in step 3, are as follows.

THE 0TH (D-C) HARMONIC NETWORK

$\omega_0=0$
$E_{s0}=0$
$V_{Ra0}=R_aI_{a0}$
$V_{La0}=0$
$V_{Rd0}=R_dI_{d0}$
$V_{Ld0}=0$
$V_{Gm0}=R_mI_{g0}$
$V_{Cd0}=(1/C_d)Q_{d0}$
$V_{Rc0}=R_cI_{c0}$
$V_{m0}=0$
$V_{t0}=-E_{t0}+r_{t0}I_{t0}$
$V_{c0}=(1/c)Q_{c0}$

where the representation of i_{k0} is I_{k0}.

THE HTH HARMONIC NETWORK ($h=1, 2, 3$)

$\omega_h=h\omega$
$\bar{E}_{sh}=E_{sh}e^{j\phi_{sh}}$
$\bar{V}_{Rah}=R_a\bar{I}_{ah}$
$\bar{V}_{Lah}=j\omega_hL_a\bar{I}_{ah}$
$\bar{V}_{Rdh}=R_d\bar{I}_{dh}$
$\bar{V}_{Ldh}=j\omega_hL_d\bar{I}_{dh}$
$\bar{V}_{Gmh}=R_m\bar{I}_{gh}$
$\bar{V}_{Cdh}=(1/j\omega_hC_d)\bar{I}_{dh}$
$\bar{V}_{Rch}=R_c\bar{I}_{ch}$
$\bar{V}_{mh}=-\bar{E}_{mh}+r_{mh}\bar{I}_{mh}+j\omega_hl_{mh}\bar{I}_{mh}$
$\bar{V}_{th}=-\bar{E}_{th}+r_{th}\bar{I}_{th}+j\omega_hl_{th}\bar{I}_{th}$
$\bar{V}_{ch}=(1/j\omega_hc)\bar{I}_{ch}$

where the phasor representation of i_{kh} is $\bar{I}_{kh}=I_{kh}e^{\phi_{ikh}}$.

Step 6. Development of Harmonic Voltage (Circuit) Equations

After the harmonic networks have been completely specified, the values of the harmonic source voltages and the linearized harmonic element parameters have been established, and the harmonic voltages represented in phasor form, the harmonic voltage (circuit) equations are written in phasor form in the same manner as for linear networks. There are H sets of voltage equations corresponding to the H harmonic networks.

Coupling between the networks is evidenced by the appearance of the harmonic current amplitudes and phase angles of other harmonic networks in the expressions for the source voltages and linearized parameters of any given harmonic network. It is because of this interharmonic coupling that the principle of superposition does not apply to nonlinear networks.

The voltage (circuit) equations for the example, in general form for the hth harmonic network with p written for $j\omega_h$, are

$$\begin{bmatrix} R_a+R_m+pL_a & R_a+pL_a & R_a+pL_a & R_a+pL_a \\ -R_m & r_{mh}+pl_{mh} & 0 & 0 \\ 0 & -r_{mh}-pl_{mh} & R_d+r_{th}+p(L_d+l_{th})+(1/pC_d) & R_d+pL_d+(1/pC_d) \\ 0 & 0 & -r_{th}-pl_{th} & R_c+(1/pc) \end{bmatrix}\times \begin{bmatrix} I_{gh} \\ I_{mh} \\ I_{th} \\ I_{ch} \end{bmatrix}=\begin{bmatrix} E_{sh} \\ E_{mh} \\ E_{th}-E_{mh} \\ -E_{th} \end{bmatrix}$$

Step 7. Evaluation of Unknown Currents

Because of the interharmonic coupling, it is necessary to solve all H sets of the harmonic voltage equations simultaneously.

In the example, the range of currents within the operating region concerned was known approximately from previous experimental work, and manual solutions were readily, though tediously, calculated by assuming values for I_{11}; minor terms were ignored in the linearized expressions and the corresponding approximate values of the other currents were calculated. A graph of the values of I_{a1}, I_{a3}, and P_{s1} versus E_{s1} is shown in Fig. 2. Values of I_a and P_s which were measured on the physical system to which the example network is supposed to be equivalent are also shown versus E_s in Fig. 2, for comparison. During stable operation the 0th and 2nd harmonic currents are zero.

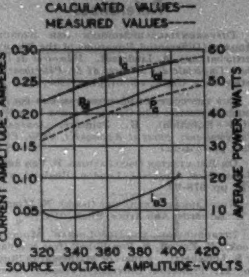

Fig. 3. Linearized parameters of the quiescent second-harmonic example-network versus the first-harmonic input current

Step 8. Verification of Stability

To confirm the fact that a specific solution represents a specific steady state, it is necessary to verify the instant and average stabilities of every harmonic network for the particular specific solution by means of the tests described in the text.

For the example network, instant and average stability were verified for every significant harmonic network within the region $0.22I<_{a1}<0.28$ ampere. Within that region every parameter of every significant harmonic network had real positive values, verifying instant stability. The verifications of average stability are illustrated in Fig. 2, where the input current and power are plotted versus source voltage. Within the region mentioned the partial derivatives of input power and source voltage with respect to input current are positive and finite for the first harmonic. The third harmonic input current is also plotted versus the input source voltage; the final upturn of that curve suggests the approach to instant instability which occurs thereafter in the second harmonic network.

The occurrence of instant stability in the second harmonic network when I_{a1} is greater than 0.29 ampere is indicated in Fig. 3. Then, l_{m2} and r_{m2} become negative if the zero and second harmonic networks are quiescent.

Discussion

G. H. Fett (University of Illinois, Urbana, Ill.): Dr. Neal has developed a compact solution to the nonlinear circuit problem which follows the technique of phasors familiar to all electrical engineers. The instant- and average-stability tests given provide a direct method of determining whether or not a particular solution is stable and physically realizable. They take the place of considerations of stability which can be obtained from the phase plane analysis for a system describable in terms of a single co-ordinate and its time derivative.

A comparison between the two methods may help to point out the advantage of the method given by Dr. Neal. In the phase plane the steady-state solution, which is the one obtained by Dr. Neal, is evidenced by a closed trajectory. Suppose that such a trajectory has been drawn for the system described by the harmonic networks, and that a small perturbation is suddenly interjected. Since the system is assumed to have a steady state, and the perturbation is small, the succeeding trajectories will approach the original one after a period of time. The parameters of the system are assumed to have changed very little and, indeed, for these average values of the parameters the Routh or Hurwitz criteria are satisfied for stability. This represents the instant stability of the paper. In connection with this statement it should be pointed out that the second sentence in the second paragraph under step 8 in Appendix II is pertinent when the equation is a polynomial in p with the highest power given as 2. When the order is higher than 2 the more specialized criteria just mentioned must be used.

Now, suppose that a large perturbation is applied to the dynamic system. The excursions in the phase plane are now so large that a significant variation in the parameters is obtained. The trajectory may not return to the original closed curve and may either become infinite in extent, to show destruction of the system, or perhaps the trajectory becomes a closed one with a much larger area enclosed. This new steady state indicates that the original configuration is unstable from the average-stability viewpoint.

To make a determination of instant and average stability, with the use of the phase plane diagram, required that the entire range of values of parameters be investigated. Furthermore, if the system had been one which required more than two coordinates, or especially more than three, the visualization of the phase space picture would be difficult. The method of Dr. Neal is straightforward, even for these more difficult problems.

It should be pointed out that Dr. Neal has taken a lot of the tedium out of the solution to the nonlinear problem with the material which appears in step 3 of Appendix II. The trigonometric terms which must be expanded and collected are already arranged for the user, including the appropriate phase angles.

Influence of Noise on Telephone Signaling Circuit Performance

LAURANCE A. WEBER
ASSOCIATE MEMBER AIEE

Synopsis: This paper reports results of a comprehensive study of influence of noise on signaling performance of the major a-c telephone signaling systems in use by the Bell System. A problem exists in the evaluation of signaling circuit performance with regard to characterization of both noise and pulsing accuracy. It appears that a good way to characterize noise is to use the 1% (per cent) point on a cumulative level distribution taken with a level distribution recorder with a 10-ms (millisecond) time constant. Pulsing performance can best be characterized by obtaining a distribution of pulse distortion while pulsing over a noise-disturbed circuit. The 2,600-cycle in-band signaling system performs satisfactorily for signal-to-1%-10-ms-noise ratios of about 0 db (decibels). The *N* carrier out-of-band system is about 6 db better than the 2,600-cycle system. While comparison is difficult due to different circuit action, the 1,600-cycle in-band system is about 10 db more sensitive to noise than the 2,600-cycle system. Some modification of signal-to-guard ratios in the 2,600-cycle system appears to result in performance which is 6 to 8 db better. Tests showed that compandor action is not detrimental to in-band signaling performance.

IN THE Bell System, signaling over toll telephone trunks is now largely obtained by a-c methods. The power of a-c signals usually is about the same order of magnitude as the speech power over the trunk so that it is true for signaling as well as speech transmission that influence of noise on performance is a limiting factor in system design. Optimum design of a toll trunk requires that the speech and signaling system withstand about the same noise before failure. Increased use is made of carrier circuits to derive toll channels. On these carrier circuits the length of repeater section is determined by the difference between maximum transmitted level and minimum received level. The first of these is a function of the power-handling capacity of the carrier system and by interference into paralleling systems. The second is a function of the system susceptibility to noise. This makes the adequate specification of performance in the face of noise of signaling circuits increasingly important. This paper reports results of a comprehensive study of the influence of noise on signaling performance of the major a-c signaling systems used by the

Bell System. These are the 1,600-cycle and the 2,600-cycle single-frequency systems;[1] and the *N*- and *O*-carrier 3,700-cycle single-frequency system.[2]

Toll-telephone signaling schemes in the United States have generally used simple amplitude-modulation subcarrier methods. The circuits in this study are of this type. Some important use of frequency-modulation and frequency-shift methods have been reported.[3,4] It has been shown that such circuits have a slight noise advantage over simple amplitude-modulation methods. Generally, however, the amplitude-modulation systems are more attractive from a cost standpoint and so have so far been used in all major trunk signaling schemes in the Bell System. Future developments may, of course, change this picture. The amplitude-modulation signaling schemes in use can be divided into in-speech-band circuits and out-of-speech-band circuits.

In-band circuits signal on a binary basis with a single frequency in the voice band (usually 1,600 or 2,600 cycles). This tone is removed during the normal subscriber talking interval so that no interference is obtained and the full voice-frequency range is available for talking. Where certain calls, e.g., to intercepting operators, require conversation while signaling tone is transmitted, the voice-frequency band is modified to provide elimination of the signaling frequency toward the customer. In this type of design it is necessary to prevent signal imitation by speech from falsely operating the signaling receiver. Special problems also arise when sending line-busy flashes and audible busy back tone. The outstanding advantage of the scheme is that it can be applied over multilink connections of differing facilities such that d-c signal repetition is not required at intermediate points. For example, a trunk from Boston, Mass., to Chicago, Ill., may consist of a *K*-carrier channel from Boston to New York, N. Y., and a *TD2* microwave channel from New York to Chicago with voice-frequency interconnection of the two channels on a permanent basis at New York. For this case, in-band signaling allows the signaling channel to be interconnected with the voice channel at New York without additional equipment. This produces a degree of flexibility, and also reduces the signaling equipment when the trunk circuit contains more than one link. The 1,600- and 2,600-cycle single-frequency systems are of the in-band type.

Out-of-band schemes are characterized by a division of the available transmission band width into a voice channel and a signaling channel. The 3,700-cycle single-frequency system used with *N*- and *O*-carrier systems is typical of this type.[5] In this system the voice band is limited to about 3,100 cycles by means of low-pass filters and a channel at 3,700 cycles is used for on–off binary signaling. This general scheme is attractive where the signaling circuit is integral with the carrier system physically since low cost and simplicity usually result. These carrier systems generally are short-haul types where it is not expected that many multilink facilities are required. Fig. 1 shows a block diagram of the general arrangement of the in-band and out-of-band signaling circuits.

Characterization Problems

In connection with studies of new applications of carrier methods, a comprehensive series of tests was performed on the three signaling circuits mentioned to characterize their performance against noise of the type usually encountered in telephone practice. This performance characterization involves three problems:

1. Specification of noise in measurable terms related to signaling performance.
2. Specification of signaling performance.
3. Conducting tests to relate problems 1 and 2.

Measuring Noise

It would be desirable to place quantitative "tag" on a given sample of noise such that pulsing performance of a signaling circuit in the face of this noise will be identical with the performance of the circuit with other samples of noise having this same quantitative tag. Normal telephone noise measurement in db with respect to reference noise (dbRN) or db adjusted by a *2B* noise measuring set is not adequate because the set has an integrating time of about 200 ms to simulate the response of the ear. Usually the response of a signaling circuit is of the order of 15 to 40 ms. An rms measurement is not adequate because noise often is very peaked in character with low average levels between peaks. An rms value would give too low a measure of the noise as it affects signaling. The approach used here is to obtain the statistics of the noise sample by sampling quasipeak levels over a time and empirically selecting a significant point on this distribution as the suitable measure of the noise. This point is chosen by running a number of samples of noise with differing level distributions into a signaling circuit, obtaining equal pulsing performance for each sample by adjusting the noise level with attenuators, then finding a common level value on the distribution curve. If this value of noise level (say, in dbRN) is used to characterize the noise, then differing noise sam-

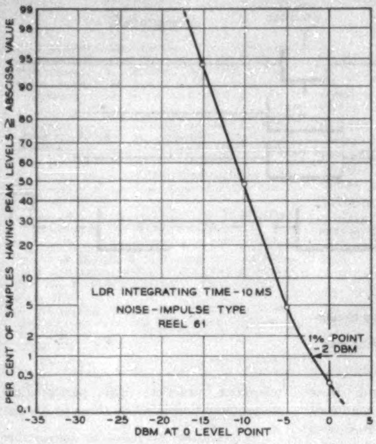

Fig. 2. Typical noise distribution from LDR readings

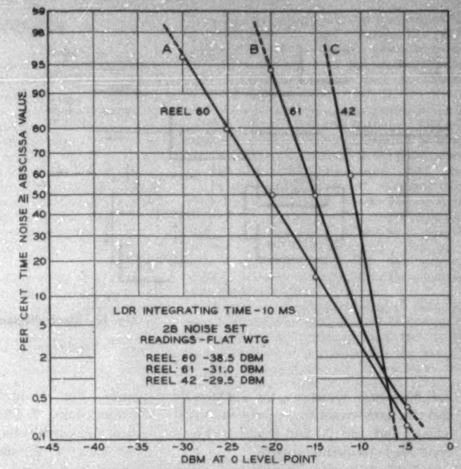

Fig. 3. LDR measurements of different noise samples; levels adjusted for equal 2,600-cyle signaling performance

ples having the same "level" will give essentially equal signaling performance. It is hoped, of course, that this "equal performance" specification for noise will be general enough to apply to all signaling circuits tested. In this study, it seemed to be the case.

A device which is convenient to use to obtain statistics of noise samples is a level distribution recorder (LDR) which has been used in previous studies.[6] This instrument samples a signal once each second, determining in this interval the peak level present over integrating times of 1, 10, or 200 ms. A bank of registers calibrated in 5-db steps indicates directly the statistical distribution of the energy level of the source. Fig. 2 shows a distribution obtained by this means of noise on a typical circuit. The plot is made on arithmetic probability paper on which linearity indicates a normal distribution.

Some distribution curves of different noise samples with levels adjusted for equal signaling performance are shown in Fig. 3. Here the differing character of the noise is readily apparent. Curve *A* represents noise having a low background level; curve *C* represents noise with a relatively continuous high level. In each case here, however, it appears that as far as signaling performance is concerned each of these samples may be characterized by the level corresponding to the 1% distribution point on the LDR curve with a 10-ms integration time. Hence noise levels can be quoted as dbRN (0 dbRN = 90 db below 1 milliwatt) at the 1% point on a 10-ms LDR distribution curve for the particular noise. To indicate the inadequacy of the *2B* noise measuring set readings, Fig. 3 also shows points corresponding to the readings on this set for the three noise samples. As can be seen, the readings differ by as much as 15 db and yet signaling is affected about the same for each noise sample.

Noise is somewhat elusive on telephone lines so that obtaining samples for testing purposes is a problem. This study utilized tape-recorded samples which were made at appropriate periods during high noise intensity on the lines. LDR distributions obtained while recording and from the playback of the tape served to assure faithful recording. Two types of noise are of interest in the signaling problem: noise originating from atmospheric static and noise generated by switching transients in central offices. The static noise generally has larger peak amplitudes but central office noise is bothersome over longer intervals during the year. Both types of noise must be considered in evaluating signaling circuit performance.

Measuring Signaling Performance

The condition most influenced by noise for a signaling circuit is the dial pulsing condition. Here rapid alternations between the binary on–off conditions transmit the digital information of a telephone user's called number; an error will cause misdirection of the call. It is natural then for the performance of the circuit to be evaluated under pulsing conditions. In the absence of noise a signaling circuit will pulse at a speed and on–off ratio determined by the source of pulses feeding it. The effect of noise will be a jitter in the on–off ratio of varying amounts. This jitter is measured in terms of per-cent break distortion or bias, where, in the system studied here, per-cent break is defined as

$$\text{per cent break} = \frac{\text{tone-on time}}{\text{tone-on time} + \text{tone-off time}}$$

For high noise levels the single pulse distortion will be high and more pulses will be distorted. At low noise levels the reverse will be true. A cumulative distribution plot of numbers of pulses distorted by given amounts on probability paper is a convenient way to characterize signaling circuit performance. Families of such curves can be plotted, showing distortion characteristics for different noise levels and for differing noise samples. Information of this type is a valuable tool to use in maximizing certain circuit parameters to obtain optimum noise immunity. Useful comparisons can be made between signaling circuits by adjusting noise levels so that equal performance plots are obtained and a rough equivalency is established between circuits. This is the pro-

Testing Procedure

For the noise measurements, an LDR is used as discussed. To measure signaling distortion, an interval timer is used. This device, developed at Bell Telephone Laboratories by O. R. Miller, generates an accurate linear ramp function. Using this, a translation of pulse duration into an amplitude function is obtained which is then detected by a group of biased amplitude gates. The gates in turn trigger a bank of registers which present a cumulative distribution curve of deviation in pulse duration or per-cent break output from a signaling circuit. Fig. 4 is such a distribution. A block diagram of the timer is shown in Fig. 5. The instrument design permits the use of different time bases, different time interval separations between registers, and a centering adjustment such that the zero distortion register may be set at any pulse duration or per-cent break output desired.

With these devices as the primary measuring instruments, a test setup shown in block diagram on Fig. 6 was assembled. The arrangement consists of a stable source of pulses variable in per-cent break and speed; an Ampex *400A* tape recorder as a noise source, a 4-way bridging pad for mixing and level measurement purposes, the single-frequency signaling circuit under test, the interval timer for pulse distortion distribution data, and appropriate gain and loss to adjust system levels. Provision is also made to insert an *N*-carrier channel unit voice-frequency section in the transmitting and receiving paths to check the 3,700-cycle signaling circuit of this carrier system and to per-

mit evaluation of the effect of the *N*-carrier compandor on the signaling-noise problem.

Performance of 2,600-Cycle Signaling Circuit

The 2,600-cycle signaling system is the current standard in-band toll signaling circuit in the Bell System. Some special characteristics of this circuit should be understood, however, before pulsing performance can be discussed. Since this is an in-band signaling circuit, it is necessary to prevent signal imitation by speech. This is accomplished by providing a guard circuit which is responsive to all voice frequencies except the signal frequency, a signal circuit which is responsive to the signal frequency (2,600 cycles), and a detector which is responsive to the difference between the signal and the guard circuits. Speech often contains components of signaling frequency but nearly always contains components in the guard band at the same time. The signal-guard responses are adjusted so that no false operation is obtained for this case. The response of the signal and guard channels of the 2,600-cycle signaling circuit is shown in Fig. 7 taken after Weaver and Newell.[1] When a composite wave of signal plus noise is impressed on this circuit, the noise in the wide guard band will tend to prevent the circuit from responding while the signal and noise in the signal band will act in the direction to operate the receiver. It would be expected then that the particular characteristic of the signal-guard band shapes would affect the pulsing characteristics and this is the case. Guard voltage due to noise will tend to delay the operation of the receiver and will hasten its release when a tone pulse is removed since it is in a release direction. It can be predicted then that generally pulses will be shortened by the action of the signal-guard detector. A shortened "on" pulse corresponds to a downward distortion in per-cent break of dial pulses.

Another factor affecting performance is introduced by the pulse corrector incorporated in the signaling circuit. The pulse corrector is designed to shorten long pulses and to lengthen short pulses about a mean of approximately 58% break at ten pulses per second.

With these factors in mind, some typical pulsing performance curves for various signal-to-noise ratios (S/N) are presented in Fig. 8. The ordinate is per cent of pulses having distortion equal to or less than the abscissa value of distortion in per-cent break below 58% at ten pulses per second. Each curve is labeled with applicable S/N ratio defined as:

$$S/N \text{ in db} = \begin{array}{l}\text{2,600-cycle signal level in db}\\ \text{referred to 1 milliwatt}\\ -1\% \text{ point on the 10-ms LDR}\\ \text{noise distribution in db referred}\\ \text{to 1 milliwatt}\end{array}$$

An interesting feature of these data is the nonsymmetrical distortion about the nominal per-cent break. Nearly all pulses are distorted downward in per-cent break. This is attributed to the action of the guard circuit. These data allow computation of lost calls if system S/N levels are given. Alternatively, if lost-call performance is specified, limiting S/N can be obtained. For example, with a system S/N level of −5 db, 0.04% of pulses will have a distortion equal to or greater than 14% break. This would be a failure point when pulsing into step-by-step switches which have a limit of 44–72% break. With this limit, one pulse in 2,500 will be missed. This can be translated into lost calls by observing that 2,500 pulses correspond to about 2,500/35 = 71.5 calls since an average 7-digit

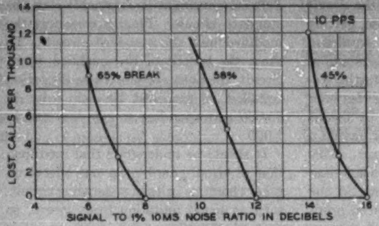

Fig. 10 (above). 1,600-cycle signaling circuit performance with impulse noise

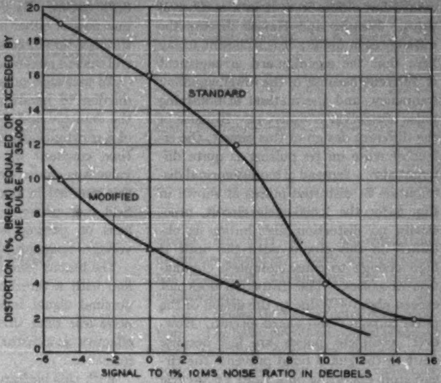
Fig. 12 (right). 2,600-cycle signaling circuit; pulsing improvement with modified signal-guard ratio



number will contain about 35 pulses. This is obviously submarginal performance but a similar calculation for an S/N of $+5$ db gives a lost-call ratio of better than one call in 1,000. This is quite adequate performance, especially since the noise used to obtain the data of Fig. 8 represents that occurring during the most disturbed periods.

Fig. 9 shows the effect of pulse correction on performance. On this curve is plotted a cumulative distribution of distorted pulses against distortion in per-cent break with three different input pulse on–off ratios. Curves are shown for 10-pps (pulses per second) 45% break; 10-pps 58% break; and 10-pps 65% break. In each case in Fig. 9, zero distortion corresponds to the steady output pulse per-cent break without noise. The distortion is measured in percentage points above or below this value. At large distortions, more pulses are distorted for the 58% break condition than for the other two. The lengthening of short pulses and shortening of long pulses is thus apparent.

Performance of 1,600-Cycle Signaling Circuit

The 1,600-cycle signaling circuit was a forerunner of the 2,600-cycle circuit dis-

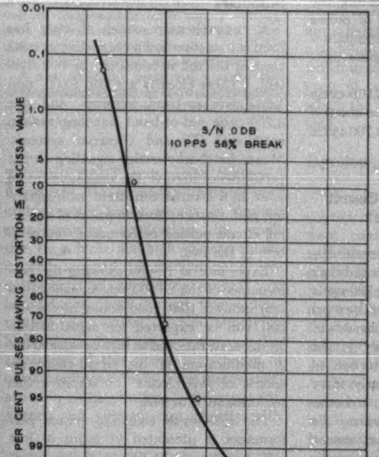


Fig. 11 (left). 3,700-cycle signaling circuit pulsing performance

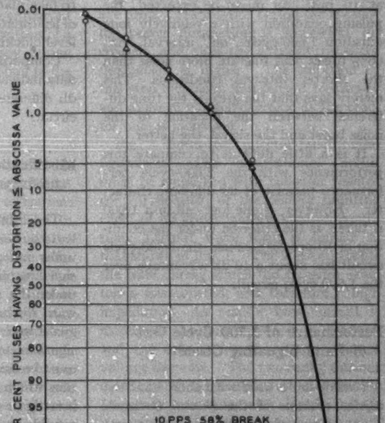

Fig. 13 (right). 2,600-cycle pulsing performance showing effect of compandor cussed but differs from it in a number of ways. Weaver and Newell discuss the differences in detail; it is sufficient to say here that the signal-guard arrangement is different because of the lower signaling frequency, and the method of obtaining pulse correction is different. Because of the different design of this circuit, the effect of noise on its pulsing is quite different also. Instead of a quasinormal distribution of distorted pulses as shown in Fig. 8 for the 2,600-cycle circuit, practically no distortion distribution is obtained on this circuit until the noise is high enough to cause complete elimination of pulses. The distortion does not exceed about 4% due to the action of the pulse corrector and guard circuit. However, complete pulses are lost because noise in the guard band prevents the circuit from operating on a valid 1,600-cycle signal. The test arrangement used with the 2,600-cycle circuit is not adequate to measure the performance of this circuit; nor is the distribution plot of Fig. 8 adequate to specify this performance. Instead, simple pulse counters on the sending leads and receiving leads were installed. The numbers of lost pulses for various S/N levels are then plotted. Fig. 10 is such a plot. Here the number of lost calls per 1,000 is plotted against the signal-to-1%-10-ms-noise ratio. One lost call per 1,000 is defined as one lost pulse in 35,000 pulses. In Fig. 10, data are shown for 45, 58, and 65% break inputs at 10 pps. As might be expected, the pulsing condition with a relatively long duration 1,600-cycle "on" interval, viz., 65% break, can tolerate more noise than the shorter interval conditions. This merely says that the greater the time difference between the duration of the noise burst and the signal, the better.

It is a little difficult to compare this performance with the 2,600-cycle performance because of its different character. However, if one lost call in a 1,000 is taken as the criterion under the condition of 10-pps 58% break, the 2,600-cycle circuit has about a 10-db advantage over the 1,600-cycle circuit.

Performance of 3,700-Cycle Out-of-Band Signaling Circuit

This circuit is used with short-haul toll carrier systems of the *N* and *O* types. This scheme of signaling is simple and straightforward as shown in the block diagram of Fig. 1. Three parts of the circuit need some mention to set the noise performance data in proper perspective.

The band-pass filter has a pass band of about 100 cycles, 3 db, down-centered at 3,700 cycles. By the nature of the circuit any power, either signal or noise, getting through this filter will act like signal and will cause a skewed distortion distribution.

To minimize noise effects, a further reduction in bandwidth is made between the detector and d-c amplifier by means of a resistance-capacitance filter having a time constant of about 12 ms. This value was chosen because delays less than this resulted in poor performance in the field and greater delays introduced problems of pulsing stability with battery voltage, temperature, and time.

The limiter used in this circuit is a flip-flop with a threshold about 6 db below nominal signal level. This means that noise less than this amount will be less effective as a disturbing influence on performance.

With this background, Fig. 11 presents experimental results on pulsing performance of the *N*-carrier 3,700-cycle out-of-band signaling circuit. The most interesting aspect of this plot is that it is skewed in the upward direction of distortion. The effect of noise is generally to increase the per-cent break of pulses. This is expected because noise occurring at the end of a pulse will give the impression that the signal pulse remained just a little longer than it actually did. Similarly, noise occurring in the tone-off interval just prior to the pulse will look like a legitimate signal anticipating the regular pulse. For shortening of pulses to take place there must be a cancellation of legitimate signal by noise, or some high-level blocking must occur.

Comparison of 2,600- and 3,700-cycle data indicates that there may be about 6 db difference in favor of the 3,700-cycle circuit.

Modification of 2,600-Cycle Circuit for Improved Performance

The 2,600-cycle signaling circuit distorts pulses downward in per-cent break under noisy conditions; the 3,700-cycle signaling circuit distorts pulses upward under the same conditions. The downward distortion is due primarily to the guard action; the upward distortion to signal imitation by noise. Clearly there must be some optimum signal-guard relation which maximizes performance. To investigate the amount of improvement possible, a 2,600-cycle circuit was modified experimentally until best performance was obtained. The modification of course effectively reduced the guard action just sufficiently so that the average signal imitation by noise was canceled by guard action. Approximately, a 6- to 8-db improvement is obtainable over the standard circuit. Fig. 12 compares the modified and the standard circuit. To show the benefit of the modified guard circuit, the data are plotted as distortion equalled or exceeded by one pulse in 35,000 corresponding to one lost call in 1,000.

It should be understood that modification of signal-guard ratio has effects on other characteristics of a signaling circuit, such as signal imitation from speech, so that whether this entire improvement is actually obtainable depends on factors other than noise. The present 2,600-cycle signaling circuit has worked well in the toll network for a number of years so it is not proposed to modify existing circuits. Future developments, however, will make use of this signal-guard optimum design.

Compandor Action on Signaling

On *N*- and *O*-carrier systems, the in-band signaling systems must send signaling tone through the system compandor. A subsidiary result of these tests presents data showing that the action of the compandor on signaling is minimal. Fig. 13 shows typical data for the 2,600-cycle system. The differences obtained between the two conditions are insignificant.

Summary

A comprehensive series of tests has been run on standard a-c signaling circuits used in the toll network of the Bell System. These circuits are the 2,600- and 1,600-cycle in-band systems, and the 3,700-cycle out-of-band signaling system used with *N*- and *O*-carrier systems. Means for characterizing signaling circuit performance involve the measurement of noise in a manner consistent with signaling performance; measurement of signaling circuit pulsing performance; and relation of the two.

Experimental results showing the performance of the 2,600-cycle signaling system indicate that good action of the circuit can be expected for signal-to-1%-10-ms-noise ratios of as high as about 0 db. A modification of the signal-guard response of this circuit can improve this performance 6 to 8 db.

The 1,600-cycle signaling system performance is presented in terms of lost calls because of the nature of the circuit action under noise conditions. This circuit can be expected to be about 10 db more sensitive to noise than the 2,600-cycle system.

The 3,700-cycle out-of-band system used on *N*- and *O*-carrier systems has something less than 6-db advantage over the present standard 2,600-cycle system and about equal to the modified design. Pulses are distorted upward in per-cent break generally for this system.

N- and *O*-carrier compandor action on in-band signaling circuit performance in the face of noise is not significant.

Magnetic Regulation Transistor Power Supply

LAMBERT F. LYONS
NONMEMBER AIEE

Synopsis: The switching-transistor saturable-reactor d-c to a-c converter is often used to supply alternating current or high-voltage direct current from a low-voltage d-c source. In this application the output voltage varies directly as input voltage, and also varies with load in accordance with the power supply output impedance.

In output regulation of this supply it is usually essential to retain the high efficiency of the basic circuitry. This paper proposes a method of regulation which employs saturable reactors in the input or load circuitry of the power supply. The method provided is convenient for achieving output voltage compensation with supply voltage drift and variations in load current. For closer regulation of output voltage, a silicon diode voltage reference may be utilized.

A method is also presented whereby the output frequency may be controlled magnetically in a-c motor and magnetic-amplifier applications.

IN AIRCRAFT and missile electronic systems, the switching-transistor–saturable-reactor power supply is finding ever-increasing application. Its small size, ruggedness, and high efficiency make it well adapted to medium-power requirements of alternating current, or high-voltage direct current from a low-voltage d-c source. When supplying high-voltage direct current, a major disadvantage of this circuit is variation of output voltage directly with supply voltage. In a-c applications both output frequency and voltage vary directly with supply voltage. Output voltage also fluctuates with load current because of transistor, transformer winding, and rectifier resistance.

It is often desirable to regulate the d-c output voltage or the a-c output voltage and frequency of such a power supply. In systems where this type of power supply is used, space, weight, and transistor power-handling capacity are limiting factors. Therefore, efficiency is of major importance. A variable-series dissipative element employed for regultion is thus not satisfactory. It was determined that a switching-type device must be employed which would vary the percentage time of a cycle of power supply frequency during which the output voltage is applied to the load.

Development

Two types of switching devices for series control of power supply input or output were considered in this investigation: transistors and saturable reactors. In applying the switching transistor to the power supply output, the transistor voltage rating was a limiting factor. For this reason, and the fact that saturable reactors are readily controlled, it was decided to develop a magnetic regulator.

Three configurations were considered: reactors in series with the transistor bases, reactors in series with the transistor collectors, and reactors in series with the output rectifiers for d-c supplies. In each of the three circuits, current flows through the reactor during half of the cycle, driving it to saturation. During the next half-cycle, current is essentially switched off and the reactor can be reset by a control current. In this respect the circuit functions as a self-saturating magnetic amplifier. Each configuration has particular advantages for certain applications.

Fig. 1 shows the base reactor configuration. The basic circuit employed is somewhat modified from the conventional power supply, in order that the collectors might be grounded for more efficient heat dissipation. Resistors *R1* and *R2* are base current-limiting resistors. Resistor *R3* provides a forward bias on one transistor, to insure starting. The power in the base circuit is comparatively low, requiring small reactors for control, and providing high control sensitivity. This sensitivity is lowered somewhat by base current under transistor cutoff condition. The output wave form of the circuit is as shown. The step at the beginning of each output half-cycle represents the time during which the base reactor is unsaturated and causes low base current and consequently a large transistor voltage drop. During this period the transistor power dissipation is somewhat increased, and thus the average transistor dissipation is higher. The duration of this step increases, and output frequency and average voltage decrease as the reactor bias is increased.

Fig. 2 shows the collector reactor configuration. The conventional circuit must be employed with collector reactor control because of the reactor shunting effect of *R3* under transistor cutoff condition. Output wave form is similar to that shown in Fig. 1. The step represents the time during which the collector reactor is unsaturated, and therefore a high impedance. As reactor bias current is increased, the step increases in duration and the output frequency and average voltage decrease. The two configurations described afford a means of maintaining frequency constant with input voltage variations in a-c power applications.

Fig. 3 shows a high-voltage d-c supply with reactors in series with the rectifiers. The frequency and wave form on the secondary of the transformer is a square wave, and is not appreciably altered by reactor bias. The voltage wave form

Fig. 4. D-c output transistor power supply employing magnetic regulation

across a resistive load, however, is a square wave with the leading edge of each half-cycle delayed. The duration of this period of essentially zero voltage varies with reactor bias, and represents the time during which the reactor is unsaturated and presents a high series impedance. A reactive load, such as a choke input filter, will vary the shape of this wave form considerably. However, the voltage integral which the reactor will absorb with a given bias is still the same.

An advantage of this configuration is that the power supply frequency and output voltage are not changed appreciably by operation of the magnetic regulator. Thus an unregulated supply can be provided from the same transformer.

Design

Basic Power Supply

Some sources for design information on transistor-magnetic power supplies are listed in the references. Detailed basic power supply design therefore will not be considered in this paper. Reactors employed in any of the three configurations serve only to decrease the output voltage in accordance with reactor bias. In an unbiased condition the reactors remain saturated, and the circuit functions as a basic power supply, with the exception of the voltage drop across the reactor winding resistance, which is very small with well-designed reactors. Thus the power supply should be designed to supply the maximum current required when the d-c input supply voltage is at minimum operational value. To ensure adequate regulation, the output voltage under these conditions should be about 5 per cent above the desired regulated output voltage.

If a filter is employed for d-c output, it must be of the choke input type, in order to prevent high surge currents in the transistors. Current surges resulting from a capacitor input filter would exceed the saturation current of the transistors, greatly increasing their power dissipation. A small input capacitor may be required for better switching action, while the choke input characteristics are still maintained.

Reactors

The reactors employed must be designed to absorb the difference between the desired output voltage and the output voltage E_{outmax}, under conditions of maximum input voltage and minimum load current. The reactor square-wave voltage rating E_r is determined from the following.

Base Control

$$E_r = E_b(1-a) \qquad (1)$$

where

E_b = base driving voltage
a = ratio of regulated voltage output to maximum output

Equation 1 affords a reactor design for preliminary test only, since base reactor control is greatly dependent on output filter and load characteristics. Final reactor voltage rating is best determined by experiment in particular applications.

Collector Control

$$E_r = E_{\underset{\text{max}}{\text{in}}}\frac{1-a}{a} \qquad (2)$$

where

$E_{\underset{\text{max}}{\text{in}}}$ = maximum power supply d-c input voltage

Output Control

$$E_r = E_{\underset{\text{max}}{\text{out}}}(1-a) \qquad (3)$$

The reactor power or "gate" winding in magnetic amplifier terminology is calculated from the following equation:

$$N = \frac{E_r 10^8}{4FB_mA} \qquad (4)$$

where

N = number of turns
E_r = reactor design voltage
F = power supply frequency with maximum supply voltage
P_m = saturation flux density of core in gauss
A = core cross-section area in CM^2

Standard tape-wound cores of Arnold Engineering Deltamax and *4-79* Mo-Permalloy, or Magnetics, Inc. Orthonol and Hi-mu *80* are used. One-mil material is recommended for frequencies as high as 3,000 cycles.

Small cores afford high sensitivity and high unsaturated reactance, but cause high winding resistance and I^2R loss, since the number of turns required for a

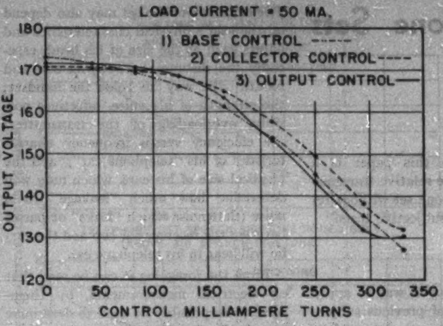

Fig. 5. Reactor control characteristics

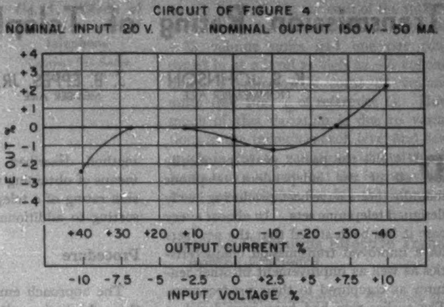

Fig. 6. Voltage regulation without diode reference

given voltage increases with core size reduction. Core selection is in general a compromise between control sensitivity and gate-winding resistance.

Load and Input Voltage Compensation

The gate winding and a test control winding (50 to 100 turns) are placed on the cores. With nominal input voltage and a constant load current, the output voltage versus ampere-turn control curve is plotted. With control windings open, the output voltage versus output current curve is then plotted.

Input voltage compensation is achieved by applying a bias current to the reactor derived from the input voltage. Since this current varies directly with input, there is automatic compensation. If this compensation is not sufficient to make the output voltage essentially constant, the bias current variation may be increased to the desired value by placing a silicon diode of the proper zener voltage in series with the input voltage bias winding and current-limiting resistor. (See Fig. 4.) The number of turns on this winding shall be chosen to maintain the bias current within the zener current rating of the diode. Final adjustment is made by the series resistor.

The required load current compensation can be determined from a consideration of the two curves. These windings are connected in series with the choke for a d-c supply, as shown in Fig. 4. This positive feedback generally is only a few turns, and can be finally adjusted by test. The control winding turns should be adjusted so that, with minimum input voltage and maximum output current, the ampere-turns from the input voltage and the ampere-turns of load current should approximately cancel each other and thus maintain the reactors in a saturated condition. With maximum input voltage and minimum output current, the net effect should be full reactor bias.

Voltage Reference

The control characteristic of the saturable reactors is not linear, and consequently there is some variation of output voltage with input and load. Temperature changes will likewise cause a drift in output.

Final regulation of the order of 1 per cent or better can be achieved by the addition of a silicon-diode reference unit with temperature compensation, as shown in Fig. 4. Additional reactor windings are provided for this purpose. An isolation choke is also provided to minimize alternating current in the control windings.

Performance

The circuit configuration of Fig. 4 was employed for test purposes, and the following components used:

transistors, Sylvania *GT-731*
supply frequency, 1,500 cycles at 20 volts input
silicon reference diodes type *IN203*
rectifiers, two *IN93* germanium and two *IN337* silicon
reactors, Magnetics, Inc. *50176-1D*
filter, 0.015 microfarad, 0.250 henry, 1.5 microfarad
input voltage,–20 volts±10 per cent
output voltage, 150 volts
output current, 50 milliamperes±40 per cent

Fig. 5 shows the control characteristic with an input of 20 volts and a 50-milliampere load. Fig. 6 shows regulation characteristics without the silicon-diode reference unit in the circuit. With the silicon-diode reference unit connected, regulation was 1 per cent. Efficiency at high-current levels was 75 to 80 per cent, a value only slightly lower than that achieved without the regulator. The regulator was also tested, using the configurations of Figs. 1 and 3 (with different reactor gate windings). Control characteristics are included in Fig. 5.

Regulation was adequate in all three test circuits, but increased transistor dissipation was noted in the base control configuration, since operation in the high-dissipation region between transistor saturation and cutoff is necessary during a portion of the cycle.

Conclusions

The transistor–saturable-reactor power supply can be effectively regulated through the use of saturable reactors. The high efficiency, small size, and ruggedness of the basic supply is retained. Regulation is achieved through input voltage compensation, load compensation, and final regulation, using a silicon-diode voltage reference. Either load or input compensation can be employed singly in special applications. In a-c power systems, power supply frequency can be stabilized as well as output voltage.

Transmission Rating of Telephone Sets

K. S. JOHNSON
NONMEMBER AIEE

J. B. EPPES, JR.
MEMBER AIEE

DURING the past 2 years practically all of the independent telephone manufacturers have been producing newly designed telephone sets. In almost every case it has been stated that the new sets have improved transmission characteristics as well as improvement in other features as compared to their predecessors. The earlier sets had been considered as "standard sets" for transmission design purposes by most large operating companies.

Every telephone operating company which was a prospective user of one of these new sets was faced with the problem of evaluating its transmission performance.

Since the transmission design of a telephone system is predicated on the use of telephone sets having a specified transmission rating, it is important that an accurate rating of the set be known. As direct distance dialing spreads to more and more independent operating companies, the importance of industry standards to help achieve proper transmission design of exchange plant will increase. At present, unfortunately, there are no known published industry standards to assist a prospective user in evaluating a new telephone set design. It is the intent of this paper to present a method of determining the transmission rating of a telephone set under various line and room noise conditions, which can be applied to any two telephone sets which are to be compared. A further objective is to present a means of correlating the results with any other method of rating.

The mechanical design features of a telephone set can be readily evaluated but the proper transmission rating is more difficult to determine. Telephone-set transmission ratings are usually determined by a combination of electroacoustical and subjective tests. Both types of tests are costly and time-consuming and it is extremely difficult to obtain results which can be reliably compared. The method described in this paper is a means of obtaining the relative transmission rating of a telephone set without resorting to additional subjective tests.

Procedure

The approach employed was to apply the published results of previous subjective tests to electroacoustical test data obtained from the set manufacturers. By conducting electroacoustical tests simultaneously on both the new design and the earlier "standard set," or some other well-known set, directly comparable data could be obtained. Existing subjective test data could then be applied to the differences in responses between the two sets in order to determine their relative transmission efficiencies.

A specification was developed for electroacoustical testing which was based on American Standards Association standards and the Bell Telephone Laboratories' artificial voice and ear test equipment. The data needed included frequency-response curves of the over-all set showing transmitting, receiving, and sidetone levels when the set was connected successively to typical long and short loops and was energized by means of a conventional battery supply circuit.

Field of Application

The method of rating telephone sets which is described herein is considered to be particularly suited to rural plant. This type of plant is mostly of open-wire construction and involves long high-resistance loops with relatively high line noise and battery supply losses.

General Considerations

The problem of rating a telephone set is a complicated one since the transmission efficiency of the set depends to a great extent on the individual characteristics of the user. Consequently, while electrical measurements alone can help greatly in determining the efficiency of a telephone set, the user's reactions to room and line noises, to acoustic sidetone, and to the over-all attenuation or loss of the circuit are factors which often determine its efficiency in telephone transmission. The efficiency of the set may also depend on the user's physical characteristics and habits such as the size of his head, especially the distance between his ears and mouth; the way he holds the handset; the strength of his voice, affecting, possibly, overloading of the transmitter; the efficiency versus frequency characteristics of his "telephone ear"; and the physical size of his ears, which may well determine how much "leakage" room noise (that noise which "leaks" or passes between the receiver ear cap and the ear) he will hear in his telephone ear.

From the foregoing it can be seen that no electrical measurements, by themselves, can possibly be used to determine completely the efficiency of a telephone set. Such measurements, however, are of great significance if it is necessary to rate only the relative efficiency of a telephone set in terms of some other well-known set which is in widespread use. The Western Electric type *300* set is used in some three quarters of all telephone systems in the United States and so has been taken as the basis of reference in the following quantitative discussion on the efficiency of a specific telephone set.

In developing this procedure an attempt has been made to utilize published subjective test data to the maximum practicable extent.[1–3] Figs. 1 through 3 of this paper are reprinted from references 2 and 3 by permission of the *Bell System Technical Journal.*

When talking face to face, it is generally acknowledged that how loud a person speaks depends on how well he hears himself or how loud his "received" speech (i.e., in both ears) is above that of his "received" noise. That is, his talking level is a function of the total signal-to-noise ratio by which he hears himself. For example, if he is talking in a noisy room, he will tend to speak louder than he will if he is in a quiet room, so that the listener will have the same or a larger signal-to-noise ratio and will therefore hear the talker more easily. When using the telephone, however, the talker does not know, initially at least, whether the listener is understanding him readily or not. If the listener has difficulty in hearing the talker, it may be due to various factors such as (1) a naturally weak voice; (2) a telephone set at the talker's location with a low transmitting efficiency, possibly due to a reduced amount of direct current in its transmitter; (3) a high circuit attenuation or frequency distortion; (4) a large amount of circuit noise; (5) a large amount of room noise at the listener's location; or (6) a

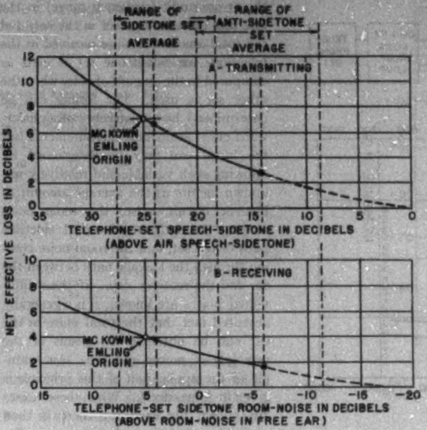

Fig. 1. Effects of sidetone on user of telephone

Courtesy Bell System Technical Journal

telephone set at the listener's location with a low receiving efficiency.

A large difference in the loss of a circuit in the two directions of speech may also make it difficult to predict the eventual level of the talker's speech. Large differences in loss frequently occur when one user is on a high-resistance loop and the other is on a low-resistance loop; they also occur on revertive calls. For example, if *A* is in a noisy room, he is likely to talk initially in a fairly loud voice. If listener *B* is in a quiet room he may hear *A* so well that he thinks the connection is a good one and he therefore tends to respond at a level that is somewhat lower than normal. Speaker *A* in turn then hears *B* poorly and tends to raise the level of his speech still further. This process may continue to build up until comments of poor reception by *A* tend to straighten matters out.

In view of the preceding, it is obviously impossible to determine the level of speech of the average talker with any great degree of precision. Although the average speech level at a local central office is reported[1] to be −19 volume units, the speech level of one per cent of the talkers comes into the central office as low as −33 volume units and one per cent comes in at a level as high as −5 volume units, a variation of some 28 volume units (see Fig. 1 of reference 1). How much of this variation is due to variations in the talker's speech level and how much is due to variations in the circuit losses is not known, but the former variations are probably by far the larger.

Basis for Computing Effective Transmitting Efficiency

The effective transmitting efficiency of a telephone set is improved by:

1. Increasing the acoustical power delivered to the transmitter unit.
2. More efficient conversion, over the audio-frequency range, from acoustical power to electric power at the output terminals of the set.
3. Reducing the acoustical sidetone level in the telephone ear of the talker.

The only known statistical data showing how a talker's speech level varies with sidetone are shown in Fig. 1 (Fig. 5 of reference 2). These data, which were derived from measurements of telephone speech over relatively short loops and tie lines, indicate that for small increases in the acoustical sidetone of an antisidetone set (type *300*) there is an effective loss due to talker's reaction of some 30 to 40 per cent of the amount of the increase. On the other hand, Inglis indicates that if the acoustical sidetone of a telephone

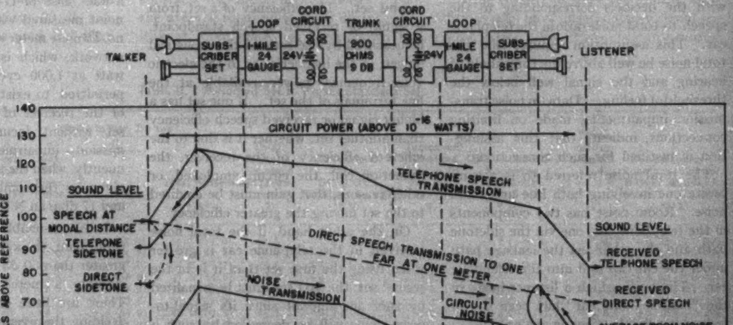

Fig. 2. Power level diagrams of typical telephone connections

Courtesy Bell System Technical Journal

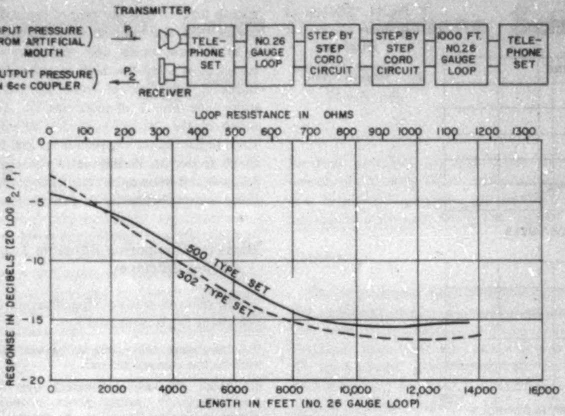

Fig. 3. Comparative sidetone levels

Courtesy Bell System Technical Journal

set under these loop conditions is reduced some 14 decibels (db) or more below that of the type *300* set, the average talker will raise his speech level only about 2.8 db. A sidetone level 14 db below that of the *300* set on a short loop is the level of natural air speech sidetone.

Basis for Computing Effective Receiving Efficiency

The proposed method for comparing the relative receiving efficiency of two sets assumes that the effective efficiency of a set, expressed in decibels, varies directly with the decibels corresponding to the speech-to-total-noise ratio in the telephone ear. This assumption requires that the total noise be well above the threshhold of hearing and the signal well below the threshold of feeling. Data on noise transmission impairments, made on limiting connections, indicate that this assumption is justified for such connections.

The total noise referred to is a composite one involving both line and room noise. Room noise has two components in the telephone ear, one via the sidetone path and the other via the leakage path under the ear cap and into the telephone ear. The noise which a listener hears in the "nontelephone ear" has been shown to have negligible effect on one's ability to receive intelligence in the telephone ear.

The receiving efficiency of a telephone set depends on: its ability to absorb electric audio-frequency power from the line; its ability to convert the absorbed electric power into corresponding acoustical power in the ear, over the audio-frequency range; and its effect on the total noise in the telephone ear.

On an average connection, where the speech-to-noise ratio is large, the impairment due to noise is not directly proportional to the noise increase. As can be seen from Fig. 1, a large increase in sidetone room noise results in only a relatively small net effective loss. However, in situations where the signal-to-noise ratio approaches that of a limiting connection, a one-to-one relationship is assumed to exist between the signal-to-noise ratio of one set as compared to that of the second set. The efficiency of a set, from a signal or received speech standpoint, is measured by the ratio of the acoustical output in the listener's ear to the electric voice-frequency power available at the line terminals of the set. If one set has a higher signal or received speech efficiency than another set, whether it is due to the inherent efficiency of the receiver, the induction coil, the circuit employed, or other reasons, that gain must be credited to the set having the greater efficiency.

On the other hand, if the total noise received in the telephone ear is greater when using the first set than it is in the second set, the first set must be penalized by such an amount since its signal-to-noise value will be decreased by such a fact. Consequently, the problem of finding the relative merits of two telephone sets, from a receiving standpoint, depends essentially upon, finding the relative efficiency of each set in converting the available voice-frequency electric power (over the entire audio-frequency range) in the line into acoustical power in the ear, and the total amount of noise received in the telephone ear when one set is used as compared to the amount of noise when the other set is used. The former can be determined by relatively straightforward electroacoustical measurements but the latter can only be determined by knowing such variable and relatively unknown factors as the average amount of line or circuit noise, the room noise coming through the electrical sidetone path of the set, and the room noise coming through the leakage path between the ear and the receiver cap. If these individual noises are known, it is a generally accepted fact that the total noise in the ear can be obtained by means of the principle of power addition. An example of the application of this principle is given in Appendix I. When these noises are known for each set there is then available all information necessary for rating the relative receiving efficiencies.

The problem thus resolves to determining the average values of the line and room noises that should be assumed to exist in the plant in which the set is to be used. A number of large metropolitan systems assume that a room noise of 40 db rap ("reference acoustic power" which is 10^{-16} watts per square centimeter in a plane wave, and corresponds to a sound pressure of 0.0002 dyne per square centimeter) is a reasonable average value for residential locations and that 65 db rap is a fair average value to assume for business offices. The weighted average value normally assumed is 50 db rap. When there is a room noise of 50 db rap, a line noise of 17 dba (db adjusted, the noise measured with a Western Electric no. *2B* noise meter with the *F1A* weighting network, which is 85 db below 1 milliwatt at 1,000 cycles) is the maximum permitted to exist at the line terminals of the receiver of a standard type *300* set without incurring a noise transmission impairment (NTI). Consequently, when the total noise exceeds that given by the combination of 50 db rap and 17 dba, an NTI is incurred.

It is reasonable to assume that, in rural plant, the average room noise is not greater than 50 db rap and that 40 db is possibly a more representative figure. There are little or no data to help in deciding the average value of line noise in rural plant, but it can be safely assumed that it is materially greater than the average existing in urban and suburban plants because of the relatively large amount of open wire used in rural plant and of the lengths of exposure to power lines.

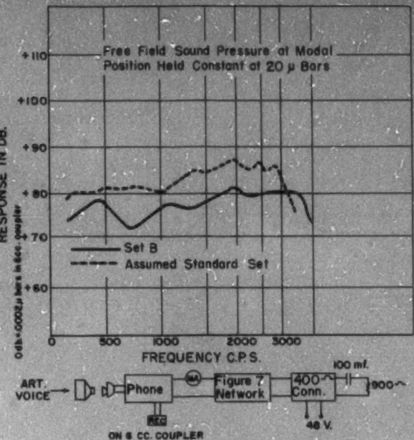

Fig. 4. Sidetone response

The best available data regarding the values of room and line noise in a typical urban connection are given in Fig. 2 (Fig. 8(A) of reference 2). The total room noise for the typical connection which Inglis assumes is made up of three components:

1. The leakage between the ear and the receiver cap.
2. The return noise or noise which is picked up by the transmitter and gets into the listener's receiver by way of the electrical (antisidetone) path of the set.
3. The incoming room noise which is the noise picked up by the transmitter at the talking end of the circuit and is transmitted over the circuit to the listener's receiver.

Unless the circuit has a very low loss or unless the noise in the room at the transmitting end of the circuit is excessively large, the incoming room noise is usually negligible as compared with other room noises. In Fig. 2 the incoming room noise, *D*, is given as about 32 db rap. When power addition is used and when some of the other noises are 40 db rap, or more, this noise is negligible in affecting the total noise in the listener's ear.

The leakage room noise, *A*, depends, among other things, on how tightly the user holds the receiver to his ear. Tests have indicated that for room noises of 45 db rap or more the leakage room noise in the ear varies slowly with changes in the surrounding noise because the listener tends to hold the receiver tighter to his ear when room noise is high. Therefore, the leakage room noise in the ear will be assumed to be substantially constant for these higher noises. For the average room noise of 50 db rap, the leakage room noise has been shown by Fig. 2 to be 45 db rap. In these tests Inglis used an artificial ear and leak. For room noises of 40 db rap or less, it is probable that the receiver is loosely held to the ear so that under such conditions the leakage room noise may be assumed to be only slightly less than that of the ambient room noise. The leakage room noise figures shown in Tables I and II were derived from these considerations.

The power levels shown in Fig. 2 were for a relatively short loop and a large signal-to-noise ratio. In rating telephone sets it is of interest to consider limiting conditions since the limiting conditions may have unsatisfactory signal-to-noise ratios. Fig. 2 assumes an acoustic

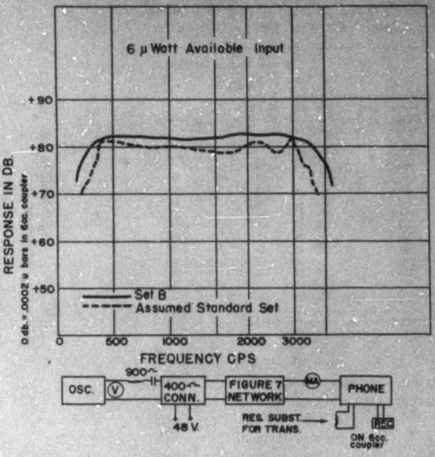

Fig. 6. Receiving response

sidetone loss of 10 db (i.e., the difference between average room noise of 50 db and a return loss, *B*, or 40 db.

For long-loop conditions which are of the greatest interest in rating a telephone set, the acoustic sidetone loss may be appreciably greater than the 10 db shown by Inglis, partly because of the greater battery supply loss of the transmitter on long loops and the anti-sidetone characteristic of the set. Data on the sidetone response of a telephone set with a typical long loop are part of the electroacoustical data obtained from set manufacturers. The way in which sidetone level varies with the loop for the Western Electric type *300* and *500* telephone sets is shown in Fig. 3 (Fig. 6 of reference 3). It should be noted that for loops of about 800 to 1,200 ohms resistance, the sidetone loss of the type *300* set is about 17 db. The fictitious standard set discussed herein has an average sidetone loss of about 17 db on a typical long loop, as shown in Fig. 4. The difference in sidetone loss for the two sets under consideration can be determined by comparing the sidetone response curves.

Several values of room and line noises were assumed in columns 1 and 2 of Table I for a typical standard set. The values in column *A* were obtained as indicated. Column *B* was obtained by considering the sidetone room noise to be 17 db below the room noise. Column *C* is column 2 converted from decibels adjusted at the receiver input to decibels rap in the telephone ear. To do this, 45 db were added to the decibels adjusted value to convert from the decibels adjusted reference to the decibels rap reference of 10^{-16} watts and 20.5 db were subtracted to allow for the loss from the receiver input to the ear (see Fig. 2, 58.5 db input to receiver and 38 db input to ear.) The last column of Table I shows the total noise in the ear, and was obtained for each combination of line and room noise by summing the corresponding values of columns *A*, *B*, and *C*, by the power addition process.

Figs. 4–6 show typical frequency-response curves for a fictitious set *B* and a fictitious standard set. These curves were assumed to have been obtained when the sets were connected through the artificial line network shown in Fig. 7 and a typical battery supply circuit. The transmitting response *t* of set *B* is shown by Fig. 5 to be about 3 db better than that of the standard set. Fig. 4 shows the sidetone response of set *B* to be about 6 db lower than that of the standard set. Fig. 6 shows set *B* to have an average gain of about 2 db in receiving response *r* over that of the standard set. The Fig. 7 network is equivalent to a typical rural line consisting of 3.41 miles of no. 22 gauge *H44* loaded cable circuit, and 5.11 miles of no. 109 steel-line-wire circuit. The loss in this network is shown in Fig. 8. The handset handle of set *B* is also assumed to be 1/2 inch shorter than the handle of the standard set. It is assumed that shortening of the handset handle results in a 2.5-db transmitting gain t_1 due to the closer coupling between the talker's lips and the transmitter unit.

With these assumptions and with the aid of Fig. 1, the effect of acoustic sidetone on the transmitting efficiency was determined. As previously stated, the sidetone level of the standard set on a typical long loop was assumed to be 17.0 db below the transmitting level, or 7.0 db below the type *300* set average indicated in Fig. 1(A). This level is 7.0 db above air speech sidetone and results in a transmitting talker's reaction penalty of 1.0 db. Set *B* would have a sidetone level 1.0 db above air speech sidetone and a transmitting talker's reaction penalty of 0.0 db. The net transmitting gain of set *B* over the standard set due to talker's reaction $= t_2 = 1.0 - 0.0 = 1.0$ db. Fig. 1(B) was not used in this rating method since the effect of sidetone as well as other noise components on receiving efficiency was included in the summation of the total noise in ear.

Tests have been made to show the effect of a 1-ringer unbalance on a multiparty line which had a moderately severe exposure to power-line induction. The results of these tests indicated that if a line is equipped with high-impedance multifrequency ringers, a 1-ringer unbalance may cause about 27 dba of noise. Table II shows how fictitious set *B* compares with a standard set. The effect of the addition of 27 dba of noise is shown by the numerals in parentheses.

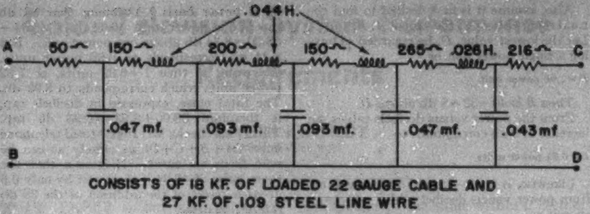

Fig. 7. Network for typical long loop

Except for these numerals it can be seen that columns 1, 2, and *A* of Table II for set *B* are identical to the corresponding columns in Table I. Column *B* of Table II was obtained by starting with the corresponding value in column *B* of Table I, adding 3 db for the more sensitive transmitter of set *B*, subtracting the 6-db increased sidetone loss of set *B*, and adding the 2-db increased receiver efficiency of set *B*. The first figure in column *B* of Table II therefore is $(40-17)+3-6+2=22.0$ db. Column *C* and the total noise for set *B* in Table II were obtained in the same manner as in Table I. The increased noise in set *B*, column *N*, was obtained by taking the difference between the total noise in the ear for set *B* and the total noise in the ear for the standard set. The received signal *S* is 2 db higher for set *B* due to the inherently more efficient receiver in set *B*. The effective gain in receiving efficiency $R=S-N$ and is shown in column 10. Column 11 shows the transmitting gain *T*, which is made up of the gain due to the more efficient transducer, *t*; the gain due to the shortened handset handle t_1; and the gain due to less talker's reaction t_2. The last column shows the net effective gain of set *B* over the standard set, expressed in the customary manner as $(T+R)/2$.

Column 10, Table II, illustrates how easily and completely a gain in the efficiency of a receiver as a transducer could be nullified by an increase in line noise such as would be caused by a 1-ringer unbalance. On the other hand, all the gain in the efficiency of a transmitter as a transducer would be effective, provided it is not accompanied by an increase in the acoustic sidetone level, or less efficient coupling between the talker's lips and the transmitter. The effect of increased line noise, of course, would be most pronounced where the line noise was the controlling noise.

From the foregoing it is apparent that the relative transmission efficiencies of any two telephone sets can be determined for any assumed values of room and line noises provided that the electroacoustical transmitting, receiving, and sidetone frequency-response curves of the two sets are known.

First, the total noise in the telephone ear must be determined by the power addition of the leakage room noise, the sidetone room noise, and the line noise. To perform this addition it is convenient to express each of these three noise components in decibels rap at the listener's ear for each of the two sets being compared. The difference in the two totals gives *N*, the net increased noise of one set over the other.

Next, the receiving frequency response curves are compared to determine the difference of one set over the other in receiving efficiency $(r=S)$. The gain in effective receiving efficiency is then taken to be $R=S-N$. The transmitting frequency-response curves are then compared and the differences between them, *t*, is corrected by the net effect of coupling between the talker's lips and the transmitter t_1, and the effect of talker's reaction t_2 due to sidetone, as obtained from Fig. 1. The transmitting gain $T=t+t_1+t_2$.

The net effective gain of one set over the other is then $(T+R)/2$ for the particular line and room noises assumed. A different value would be obtained for each different value of assumed line and room noise.

Conclusions

It is believed that the method of transmission rating of telephone sets described in this paper provides a valuable tool for use by operating telephone companies in evaluating the performance of telephone sets in their systems. It does not take the place of an industry standard method of rating, but it could serve as the basis for the development of such a standard. It is not based on arbitrary standards but on the results of subjective tests. If later subjective tests result in modifications, the method of rating can still be applied without change.

Appendix I. Power Addition of Noises

It is generally accepted that the resultant or total noise, which is composed of two or more noises of different composition, is that which corresponds to the total power of the individual noises. For example, suppose

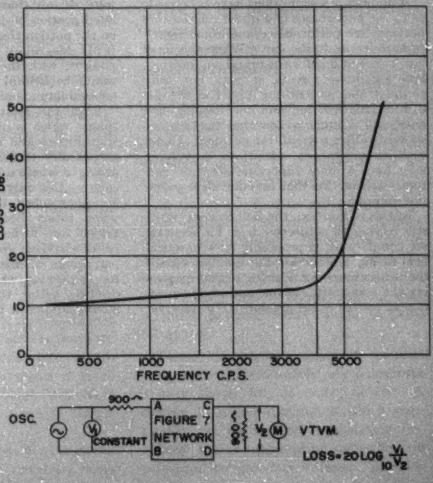

Fig. 8. Loss of network

that there are two such noises of equal power. The total power is obviously twice as great as is that of either of the individual noises. Expressed in decibels, a doubling of the power corresponds to an increase of 10 $\log_{10} 2$ or of 3 db. Hence the resultant noise in the case of two such equal powers is 3 db greater than that of either individually.

This process means that if several sources of noise exist at a given place and if one of the component noises is several decibels louder than that of any of the others, the total noise, expressed in decibels, is only slightly greater than that of the loudest of the component noises.

As a numerical example, suppose that in the receiver of an electrically short connection (Fig. 2) the component room noises are

A—Leakage under the receiver cap....	45 db rap
B—Return room noise, through the sidetone path....................	40 db rap
D—Incoming room noise, from the distant end of the circuit...........	32 db rap
C—The circuit noise at the ear*.......	38 db rap

Also, assume it is first desired to find the total room noise, i.e., the sum of A, B, and D. Let the lowest value, D, be regarded as having a single power unit or

$D = 1.00$ power unit

Then B is $40-32=8$ db above D.

From the power versus decibels tables, an increase of 8 db corresponds to

$B = 6.31$ power units

Likewise, A is $45-32=13$ db above D or, from power versus decibel tables, A corresponds to

$A = 19.95$ power units

The total number of power units in $A+B+D$ is then 27.26.

A power ratio of 27.26 corresponds to a gain of 14.34 db. Hence, the total room noise $A+B+D$, is 14.34 db above 32 db rap or is $14.34+32.00$ or 46.34 db rap.

The circuit or line noise assumed, C, was 38 db rap. In order to determine the combined or total room noise and circuit noise, the two noises must also be added together on a power basis. Assuming that 38 db rap is one power unit, 46.34 db is $46.34-38.00=8.34$ db above one power unit. But 8.34 db corresponds to 6.82 power units. The total is then $1+6.82$ units, or 7.82 power units which corresponds to 8.93 db. The total noise, expressed in decibels rap, is therefore $38.00+8.93=46.93$ db rap. This value checks Mr. Inglis' total telephone noise $(A+B+C+D)$ as closely as can be read from his curve. It is seen that the room noise of 46.34 is increased by only 0.6 db as a result of the addition of the 38 db rap of line noise.

---

* Actually this circuit noise can be increased by about 3.5 db, to 41.5 db rap without causing any NTI.

Discussion

W. H. MacAdam (American Telephone and Telegraph Company, New York, N. Y.): The paper discusses an interesting approach to the important but difficult problem of comparing the performance of different types of telephone sets. While the method is useful in indicating qualitative trends with changes of one or another of the many variables, the difficulty seems to be in obtaining quantitative agreement with transmission performance as indicated by observations and tests on actual users. Perhaps further study will develop means to produce comparable results.

A number of assumptions have been made as to the importance of a direct relationship between set performance and total signal-to-noise ratio at the ear. While this may not be out of line for the marginal, limiting-loss high-noise circuit, it may not fully consider the present-day user's desire for comfortable volume and for keeping line noise and sidetone so low that they do not seriously affect normal transmission. Under such circumstances, variations in volume may have a more important effect on customer satisfaction than an equivalent variation in noise.

In this connection, the Bell System, while still relying on subjective tests for accurate set comparison, is proposing as a practical field-rating system for the over-all circuit the measurement of acoustic pressure entering the transmitter at one end of a connection as related to the pressure at the receiver at the other end. The decision to proceed along these lines is based on the fact that the modern telephone set has a rather flat transmission frequency characteristic, and its sidetone loss is sufficiently high to keep noise or speech sidetone from becoming important.

K. S. Johnson and **J. B. Eppes, Jr.**: Mr. MacAdam indicates that transmission ratings obtained by using this method of rating may not agree with the results obtained by observations and tests on actual users. We based our method on A. H. Inglis' subjective test results (see reference 2 of the paper). The sidetone levels we considered were so low that they fell on the extrapolated portion of Inglis' curves rather than on the portion that represented actual data. If Mr. MacAdam has unpublished data that disagree with the published data used, it would be helpful to make them available for evaluation and comparison.

With the relatively flat frequency response which is obtained from present-day transmitters and receivers, we believe that satisfactory transmission will normally be achieved where a large signal-to-noise ratio exists. It is only when limiting connections are approached that noise and signal-to-noise ratios become important. For a typical low- or medium-resistance loop in a rural telephone system involving a sizeable percentage of noncable facilities, it is not too important whether one set is several decibels better than another set. A set having automatic transmission equalization, such as the Western Electric type *500* set, reduces the transmission improvement achieved by more efficient transmitter and receiver units on a low- or medium-resistance loop.

We concur with Mr. MacAdam regarding the desirability of keeping a comfortable volume and a large signal-to-noise ratio. Unfortunately, these conditions are not achieved on a large number of rural telephone circuits with long open-wire exposures to power systems.

We also concur with the desirability of subjective tests for accurate comparison of different telephone sets but feel that it is impracticable to require either the independent manufacturers or small operating companies to conduct such tests. We do not believe that measurement of the difference between the acoustic pressure at the transmitter end of a circuit and the pressure at the receiver end of the circuit would, by itself, give a valid rating of a set, under the variable noise conditions prevalent in rural telephone systems.

We would like to re-emphasize that the rating procedure described in this paper is a practical tool to enable a prospective purchaser of a telephone set to evaluate its transmission performance without resorting to subjective tests. The checks we have been able to make on its accuracy are limited, but have given us reasonably good correlation with the results of subjective tests that were available to us. We would welcome the opportunity of checking this method against the latest available subjective test data.

Color-Television-System Performance Requirements

RALPH KENNEDY
NONMEMBER AIEE

THIS PAPER is intended to cover the basic requirements which a transmission system must meet to handle a standard color-television signal. Additionally, where possible, the effects produced by departures from the ideal by various parameters will be illustrated. Three broad areas which will be covered include phase, amplitude, and transient requirements.

Phase Requirements[1]

The placing of phase at the top of the list of requirements is no accident. It actually is the most important parameter which must be considered. Some indication of the effect which phase has may be quickly realized when it is pointed out that three different types of phase relationships must be held to very close tolerances to assure good color pictures.

1. The phase relationship between the high- and low-frequency signal components must be held within ±0.05 μsec (microsecond) which is ±62 deg (degrees) at 3.579 mc (megacycles) per second.
2. The phase relationship between any color component and burst must be maintained within approximately 10 deg.
3. The phase relationship between the I and Q vectors must be 90 deg ± 10 deg. Consider each in detail.

TIME DELAY

Item I has several terms used to describe it. Perhaps the easiest way to visualize the requirement is to use the transmission time approach. It is required that the time necessary for high-frequency signal components to traverse the system be the same within a certain tolerance as is required for the low-frequency components. More precisely, all signal components having frequencies between 50 kc and approximately 5.0 mc must have identical transmission times within certain tolerances. See Fig. 1.

Needless to say, abrupt changes in the phase characteristic are to be avoided since these represent regions of the frequency spectrum where the time of transmission of certain components is markedly different from that of near-by frequencies. Indeed, the maximum extent of such discontinuities has been written into the specification and can not exceed ±0.1 μsec in certain portions of the video band. This region extends from 50 kc to 3 mc. The permissible variations decrease linearly to ±0.05 μsec at 3.579 mc above which they increase linearly to ±0.1 μsec at 4.18 mc.

Fig. 2 shows the desired phase curve.

ENVELOPE DELAY

The standard adopted for the color-system transmission-phase specification is stated in terms of the envelope or group delay characteristic.[2,3] Mathematically, envelope delay is expressed as the derivative of the φ versus w characteristic. Thus, if $\varphi=wt$, $d\varphi/dw=w\,dt/dw+t$. For an ideal system or one where t remains constant for all values of w in the domain of interest $d\varphi/dw=t$. See Fig. 3. However, when t is not a constant $d\varphi/dw$ is the sum of two terms, one of which embodies a rate of change of transmission time with respect to angular frequency. It is this term which justifies the use of envelope delay as a criterion for system performance. The derivative has the effect of magnifying the variations which are in Fig. 1 or 2. This means that the system is being subjected to a much more stringent test when it is required that the envelope delay have a particular tolerance. Conversely, a system which meets a given envelope delay requirement will have a much better appearing phase or simple time delay performance.

As is true for many physical phenomena there are drawbacks to envelope delay measurements.[4] Any realizable network has a relative φ versus w characteristic (see Fig. 2) which has a value of $\varphi=0$ or $n\pi$ radians at $w=0$ where n is a positive integer. Clearly, when $w=0$ one cannot take the derivative of $\varphi=wt$ and there results an undefined point where it is essential that the characteristic have a value.

An example will serve to illustrate. The relative phase characteristic of the side-band filter in a television transmitter is shown in Fig. 4. It rises rapidly from $\varphi=0$, $f=0$ to a frequency of about 1 mc above which it has a smaller slope in the remainder of the band. Envelope delay measurement would appear to be much better above 1 mc than below it and phase correction might appear desirable in the region below that frequency. However, prolongation of the curve back to $f=0$ (curve A) to result in φ having an integer value of π radians is remote indeed. Instead, the lower frequency portion should be considered distortionless and correction applied to the upper portion B.

What kind of a test signal will give a measure of the envelope delay characteristic? As has already been indicated, envelope delay is the angular frequency rate of change of the transmission time at the angular frequency. Since 2π is a constant, envelope delay may be written $d\varphi/df$. Now, since it is known that $\lim_{\Delta f\rightarrow 0} \Delta\varphi/\Delta f=d\varphi/df$ it becomes evident that the envelope delay is a measure of the incremental change in phase occasioned by a change of frequency as the frequency increment approaches zero in the limit. What is ideally necessary is a phase detector capable of measuring incremental changes of phase as the frequency increment becomes smaller and smaller, finally approaching zero as a limit. Further, such measurements must be made at a sufficient number of frequencies to be able to define a curve such as Fig. 3.

At this point it is necessary to depart from mathematical rigor and consider circuit practicalities. Since the phase detector cannot be expected to meet the foregoing dictates, it is necessary to ease the requirements by simply stating that it must indicate some angle $\Delta\varphi>d\varphi$ for $\Delta f>df$.

These assumptions make it possible to use conventional techniques to generate a test signal for envelope delay.[5] A doubly balanced modulator which suppresses the carrier and modulating frequency thereby generating only the two side-band components suffices. The dif-

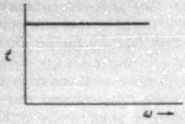
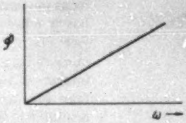
Paper 56-271, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956.

Manuscript submitted November 29, 1955; made available for printing June 8, 1956.

RALPH KENNEDY is with the National Broadcasting Company, New York, N. Y.

The author is indebted to the American Telephone and Telegraph Company, which made available the color illustrations, Figs. 11, 12, and 13. Thanks are due to Howard Gronberg, National Broadcasting Company, for making available Fig. 14, and to the late R. B. Shelby and G. M. Nixon of the NBC Engineering Department for the encouragement they have given to the writing of this paper.





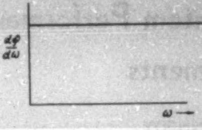


Fig. 1 (left). Ideal system time delay characteristic

Fig. 2 (center). Ideal system phase delay characteristic

Fig. 3 (right). Ideal system envelope delay characteristic

ference between these two frequencies is Δf. The phase detector must indicate the change in phase $\Delta\varphi$ between the two frequencies. Since twice the modulating frequency is Δf the absolute value of the two frequency components are the sum and difference of the suppressed carrier and the modulation frequency. As a result the test signal comprises two frequencies a constant Δf apart which scan the system phase characteristic as the carrier frequency is adjusted.

The remaining requirement for any type of phase measurement is a reference signal from the input with which to compare the output. For closed-circuit measurement, i.e., where the input and output terminals are available together, e.g., an amplifier, no problems are encountered on this score. However, for through system measurements where input and output might be miles apart, means must be provided to obtain a reference from the input to the output. Additionally, such systems are usually equipped with clamper amplifiers somewhere throughout their extent and need pulses for driving the clamps. These two requirements point to the use of pulses having a very stable frequency in conjunction with the two side-band components as a complete test signal. The two side-band components appear on an oscilloscope as shown in Fig. 5. Addition of the synchronizing signal results in a signal as shown in Fig. 6.

One device useful for making such measurement uses a 100-kc modulating signal or Δf of 200 kc and an adjustable signal generator having a frequency range from about 100 kc to 10 mc. Measurements can be made down to a frequency of about 350 kc. It should be realized that the synchronizing signal used as a reference, and which in this apparatus is 1/6 of the 100-kc signal, has higher order components with energies high enough to cause interference up to 200 or 300 kc. This acts as a lower limitation on the measurements.

The range between 50 and 350 kc needs additional investigation before thorough measurements are possible. Certainly the Δf could be reduced by using a slower rise-time synchronizing pulse so as to reduce the interference between them. However, this represents only a minor improvement. Some other approach must be found.

Such a test signal permits testing either closed or through circuits since the synchronizing pulses act as the reference signal. Closed-circuit measurements may also be made where $\Delta\varphi$ is kept constant and Δf is measured as has been pointed out by Kallman.[6]

Naturally, the question is asked: How does envelope delay affect a picture and to what extent? To answer this question it is necessary first to appreciate the effect the system having an ideal phase characteristic will produce on a signal when the system is ideally bandwidth limited. An ideal square wave will suffer deformation as predicted by Gibbs and shown in Fig. 7.

The effect produced on a square wave and additionally on an impulse has been determined by synthetic means. The synthesizer calibration is shown in Fig. 8(A) for an ideal bandwidth limited square wave and Fig. 9(A) for a $(\sin x)/x$ pulse. It is assumed that the envelope delay is constant between 50 kc and 4.2 mc. Figs. 8(B), 8(C), 9(B), and 9(C) show the effect for ± 0.05-μsec change while Figs. 10(A) and 10(B) are for ± 0.10-μsec variation. The overshoot for ±0.05-μsec variation is 14.6% (per cent) versus the 8.9% overshoot for the ideal case. This is evident as a leading or lagging black bar on the edges of any sharp black to white transitions in the picture. Tests show that 1% brightness variations are just visible; hence, nothing greater than 8.9% should be tolerated. In a color signal the same situation exists as for monochrome with the added difficulty of color being shifted with respect to outline detail. As an example, the red color of lips may be shifted with respect to monochrome lips appearing as though the lipstick had been displaced with respect to the outline of the lips. Such distortions are for envelope delay variations occurring in a uniform manner over a large portion of the frequency range.

On the other hand, abrupt delay variations occurring over rather small frequency increments in the upper portion of the video band can cause shifts in phase between various color components creating hue shift.

Differential Phase Distortion

Item 2 relates to the maintenance of close phase relationships between the various color components and between these components and burst. Departures from ideal are called differential phase distortion. In so far as the broadcaster is concerned, its cause may be summed up as due primarily to tube overloading though envelope delay distortions can also have an effect. This is particularly true for feedback circuits or circuits having slight regeneration at high frequencies.

Prior to color transmission it was common practice to give no consideration to differential phase distortion either

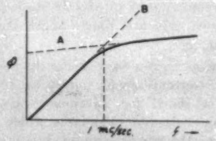

Fig. 4. Television transmitter side-band filter phase delay characteristic

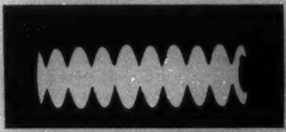

Fig. 5. Output of doubly balanced modulator

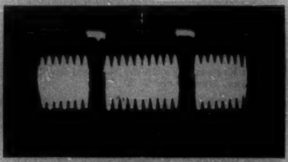

Fig. 6. Signal of Fig. 5 after inclusion of synchronous pulses

in audio or monochrome video amplifiers. It was customary to design feedback video amplifiers with 15,000 ohms in the plate circuit. The frequency response without feedback was flat to about 100 kc. The introduction of 30 to 35 db (decibels) of feedback resulted in a frequency response which was flat to 8 mc. However, the resultant improvement in the distortion applied only to the frequency band up to 100 kc. Above that frequency the amount of voltage available for feedback was decreasing and the distortion was increasing. However, the distortion did not produce too serious trouble, since the energy contained in the video signal decreased with frequency.

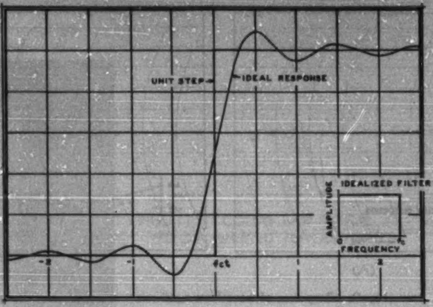

Fig. 7. Response of an ideal band-width limited system to a unit step

With the advent of color television this situation was altered when the amplifier was subjected to high-energy high-frequency components.[7] Inspection showed that a 3.579-mc test signal which is a sinusoid was warped into a sawtooth whose shape changes greatly for small changes in frequency. Fourier analysis of the wave forms showed that both sine and cosine terms were present in the series and that phase shift was introduced between the various components. It was found that the amount of phase shift was a function of the signal amplitude. Tests were devised and measurements made which showed that as much as 14 deg of differential phase shift was occurring in one amplifier. In some instances it was necessary to have six such amplifiers in a circuit.

The effect observed on a color picture which suffers differential phase distortion is one of hue shift as a function of signal amplitude.[8] In the case of saturated yellow, which is transmitted at the highest level of any component in the video signal, the color component was shifted so far in phase that it appeared green in the picture. See Figs. 11, 12, and 13.

As one would expect, the low-amplitude components, e.g., suturated blue, magenta, and red, suffered least from this form of distortion while the effect of the distortion became more pronounced for higher amplitude components.

The measurement of differential phase distortion requires a special signal. Two methods are in current use.[9] If a Radio Corporation of America color signal analyzer is used the special signal is a 15.75-kc stair step having the bottom step at black and the top step at white, modulated with 3.579-mc sine wave having a level of about 20% of peak-to-peak video. Blanking and synchronization are added to this signal to create a conventional television signal. This signal is fed through the system under test and the differential phase shift measured by means of a color signal analyzer and an oscilloscope. The measurement shows the amount of shift in phase through the system for the small high-frequency sine wave signal at different stated levels of the low-frequency signal on which it is super-imposed. Shifts in phase of less than 1 deg are readily detected.

I AND Q VECTORS

The third type of phase distortion that must be controlled is the phase relationship which exists between the I and Q vectors. This distortion occurs in an improperly adjusted colorplexer. Like differential phase distortion, it makes itself evident in the picture as a shift in hue.

The Hazeltine Vectorscope is a display device intended to show the phase and amplitude of the chroma components and reference burst as well as that of the I and Q vectors. The standard color bar signal at the output of the colorplexer will present on the face of the Vectorscope the phase relationships that are produced by the encoder.

Influence of Amplitude on the Performance of the Color System

In speaking of amplitude effects on a color reproduction, two entirely different phenomena must be kept in mind. First, there is the usual amplitude versus frequency characteristic generally referred to as "frequency response." Second, there is what is known as differential gain. This gain was called compression in monochrome television. Differential gain more rigorously stated is the difference in gain of the system for a small high-frequency sine wave at various levels of a low-frequency signal on which it is superimposed.

Frequency Response

Originally it was thought that 1% allowable difference between the burst and horizontal line frequencies would be necessary, and with ±3% maximum allowable deviation in the region between them would be adequate for ten amplifiers. Experience has shown that this tolerance need not be this stringent.

The response variation of a system causes two effects to be observed in a color picture. Manifestly, a rolling-off of the high-frequency response curve starting at too low a frequency and changing at too rapid a rate will cause the picture to appear soft in monochrome and lack detail. In color the chromanence suffers desaturation as well.

From the tolerances which have been mentioned, the question undoubtedly arises as to how such measurements are made. The oscilloscope serves a very useful purpose when a 10-centimeter trace is used. One millimeter is equal to 1% and a centimeter scale permits checking system performance to the desired tolerance. The only problem is to calibrate the oscilloscope. However, there still remains the problem of measuring individual components of a system, e. g. amplifiers, equalizers, cables, and related apparatus.

For a number of years the Bell System has used a device developed by the Bell Telephone Laboratories for making transmission measurements on video circuits. This is known as the type *70A* transmission measuring set. It is a thermocouple-operated power measuring meter having an impedance of 75 ±1 ohms. The meter is calibrated in decibels related to 1 milliwatt (dbm). The range is from −10 dbm to +3 dbm with 0 dbm equal to 1 milliwatt into 75 ohms. The scale length between +2 and +3 dbm is about 0.75 inch so that the 0.1-dbm scale designations are 0.075 inch apart. With such a scale, 0.05 dbm is easily read while values of 0.02 dbm are fairly accurately estimated. The meter has an accuracy of ±1%. The error of the meter plus meter reading error is about 1.3% in terms of absolute power; however, by using two meters for indicating relative input and output level, the measurement may be made to within less than a per cent.

Such meters not only permit making measurements on amplifiers, equalizer, cables, etc., but may be used as a standard for the calibration of oscilloscopes as well.

Differential Gain Distortion

The differential gain distortion is an indication of the compression characteristic of a circuit. The effective gamma range of the system is reduced. In a monochrome picture this form of distortion may make itself evident in one of two forms. The gamma range may be restricted in either the black or the white region. This results in a picture whose black areas tend toward gray or whose white areas tend toward gray.

A color picture may again suffer from either of the two forms of degradation. A circuit which compresses the black or restricts the gamma range in the dark portions of a monochrome picture will cause desaturation of purples and blues in a color picture. The opposite condi-

tion wherein the monochrome whites are compressed results in the same washed-out appearance in the yellow areas of a color picture.

The cause of differential gain distortion is due to operating a tube in the system in the "knee" or highly nonlinear portions of its E_g-I_p characteristic. Operating the tube in class A and utilizing feedback are effective means for reducing the differential gain distortion.

As the name implies, this form of distortion is a function of the over-all signal amplitude. The measurement of such deterioration in a monochrome signal is accomplished by using a stair-step signal. Each step of the output signal must have the same relative amplitude as the input signal. The test signal for color systems is the same as is used for differential phase distortion measurements. After passing through the system the signal is passed through a 1-mc high-pass filter. This signal, when viewed on an oscilloscope, should have the same amplitude for each step. See Fig. 14.

Transient Measurement

SQUARE-WAVE TESTING

The literature is filled with material concerning transient testing of systems. By and large, the major share of the data are directed toward the square-wave or unit-step-function type of test signal. This is doubtless due to the fact that Heaviside concerned himself with this approach and his work was the basis for most subsequent related activity.[9]

There are a number of points which must be appreciated, however, regarding transient testing. The most important is the shape of the test pulse which will reveal the greatest amount of data about a system. This, in turn, calls attention to the type of data which the system is required to handle in normal operation. In the present instance it is a color television signal. This signal is a time sequence of electric impulses created by the horizontal passage of a circular cross-sectional beam of electrons across the photo image of the object viewed by the camera. Since the beam has a finite diameter, changes of brightness, represented by vertical edges in the picture, do not cause instantaneous variations in signal output level. On the contrary the voltage output follows a sin^2 shape very closely.[10] It is apparent that a sharp instantaneous rise as described by Heaviside is not a pulse which is truly representative of the camera output. Neither is the raw output of the present-day video square-wave generators which generally have rise times of the order of 0.02 μsec a suitable test signal. Indeed, the square wave, if it is to be used, should have a predetermined rise-and-fall characteristic following a sin^2 law.

It is interesting to consider the spectrum of the ideal square wave and the sin^2 shaped square wave. The ideal square wave has components which are spaced the repetition frequency apart out to infinity. The sin^2 law causes the pulse spectrum to be 6 db down at a frequency equal to half the reciprocal of the rise time between zero and 100%. At twice this frequency the spectrum drops to zero and remains about 30 db down for all components above that frequency. Clearly, the shaped square wave has a spectrum which is a much more realistic test for the system.

As noted, the rise-and-fall time determines the spectral distribution. To test the system properly it appears that two different pulse shapes would be desirable. When horizontal line frequency used as the repetition rate, there should be one pulse having a spectrum zero at 4.0 mc and the other at 8.0 mc. This provides signals capable of evaluating the system in the middle and upper portions of the frequency band.

The measurement of transient response using square waves is more generic than specific. The display on the oscilloscope requires long and painstaking effort to acquire analytical data about a system.[11] Generally, there are four questions which can be asked about the transient characteristics of systems: 1. If the wave form of several links be known, what is the wave form when they are cascaded? 2. Given the wave form for a circuit composed of a number of identical links cascaded, what is the wave form of one of the links? 3. Given the wave form for a circuit and a part, what is the wave form of the remainder? 4. Given the response to one wave form, what is the response to

another? The answers to questions of this type are important and yet require considerable effort. The usual square-wave tests involve an attempt to measure rise time which gives a crude indication of bandwidth. The degree of nonsymmetry about the transition which is produced by phase distortion is at best only a rough approximation.

IMPULSE TESTING

The use of square waves in conjunction with wave-form correctors provides a fairly satisfactory method of equalizing a circuit for transient response. However, there appears to be considerable advantage to be gained by using the shaped impulse. Ideally it should be a $(\sin x)/x$ function. However, it is impossible to construct a shaping filter capable of producing such an ideal wave form. A $\sin^2 x$ shaping filter may be built which causes the pulse to conform to the mathematical ideal within 1%.[12] This pulse may then be shaped roughly to approximate the $(\sin x)/x$ by means of linear phase shift filters.[13,14]

The characteristic of the $\sin^2$ pulse may be related to the spectrum response as follows: When the half-amplitude duration (h.a.d.) of the pulse is equal to $1/2f$, the response is down 6 db at a frequency f. Further, the spectrum response is zero at $2f$. If f is 4 mc (the nominal television bandwidth), the h.a.d. is 0.125 μsec. The spectral response of the pulse is 6 db down at 4.0 mc and is zero at 8 mc. Further, the diameter of the smallest black or white element which can be sent over the system is equal to the h.a.d. of the pulse. See Fig. 15. Ideal bandwidth limiting causes a 13% overshoot versus 8.9% for a step function. Further, the area under the pulse remains constant for all degrees of band limiting.

The generation and display of such a pulse requires special apparatus. The generator is driven by horizontal pulses which are shaped and drive a blocking oscillator. The output is a very short duration impulse, which is formed into a $\sin^2$ pulse in a shaping filter. One of the most desirable features of this test means is the ease of duplication of the test pulse. The shaping filter which consists of five capacitors and four coils controls the entire shaping operation. So long as these elements are measured to within 1%, the pulse output deviates from the ideal by less than 1%. Clearly no problem exists in building generators having the same output wave form.

The Tektronix *524* has been used as a display means and thus far has been satisfactory for viewing the pulse out of the shaping filter. A better oscilloscope, however, is required to view the impulse into the shaping filter since it has an h.a.d. of about one fifth that of the output pulse.

The interpretation of the wave forms is quite easy. Figs. 16–20 show $\sin^2$ pulses of various h.a.d. together with the effects produced, by various degrees of bandwidth limitation and phase nonlinearities. Figs. 16(A), (B), and (C) are three test pulses having h.a.d. of 0.34, 0.17, and 0.11 μsec, respectively. These pulses have corresponding spectra down 6 db at 1.5, 3.0, and 4.5 mc. They were passed through a series of low-pass linear-phase-shift filters.[14] The filters have 3-db rejection frequencies at 6.0, 4.0, 2.3, and 1.67 mc. Figs. 17(A), (B), (C), and (D) show how the filters effect the 0.34-μsec pulse. Observe that Figs. 17(C) and (D) show a decreasing pulse height and increasing width. Also note the symmetry in Fig. 17(D) as the pulse begins to assume a $(\sin x)/x$ shape. Since the pulse contains essentially no energy above 3.0 mc, the 6.0- and 4.0-mc filters have no effect on the pulse height or duration. This is observed in Figs. 17(A) and (B).

Figs. 18(A), (B), (C), and (D) show similar bandwidth reductions on the 0.17-μsec pulse. Here reduced pulse height and increased width are very apparent.

Figs. 19(A), (B), and (C) illustrate the effect that the 6.0-, 4.0-, and 2.3-mc filters produce on the 0.11-μsec pulse. It is quite evident that the phase characteristic of the 6.0- and 4.0-mc filters is not so good as the 2.3- and 1.67-mc types as indicated by the lack of symmetry of the ripples.

Figs. 20(A), (B), and (C) show the deformation of the pulse caused by a lossless nonlinear network.[15] The particular network used was intended to produce the envelope delay characteristic for the color-system television transmitters. This requires that the envelope delay remain constant from 50 kc to 3 mc and then decrease linearly to 4.18 mc resulting in a value of 0.17 μsec at a frequency of 3.579 mc. Thus, very little, if any, effect should be produced on the 0.34-μsec pulse as is evident from Fig. 20(A). However, the 0.17- and 0.11-μsec pulses suffer increasing distortion as is evident from Figs. 20(B) and (C). Furthermore, note that the slight ripple follows the main pulse in Fig. 20(A) while it precedes the pulse in Figs. 20(B) and (C). If the network has an increasing time of transmission with frequency (the opposite of the network used), the location of the ripple is reversed. This reveals the type of phase shift present in a system.

In Europe where sin² testing techniques have reached a high degree of precision, a system test signal is in common use which consists of four different wave forms. The low-frequency portion of the system is adjusted by use of a 50-cycle square wave. This corresponds to the 60-cycle square wave in the 525-line system.

In addition, a conventional television signal is generated which consists (for the 525-line system) of a 30-μsec shaped bar having amplitude of standard black-to-white video. On the same horizontal line and preceding the bar is inserted either of two sin² pulses. One pulse has an h.a.d. of 0.125 μsec and the other is 0.25 μsec.

This combined test signal provides a ready means of ascertaining the streaking or smearing potential of a circuit which occurs in the frequency region from 15 kc to a few hundred kc. This is indicated by the 30-μsec bar. By having a rise and fall the same as the 0.25-μsec h.a.d. sin² pulse the bar will contain components 6 db down at 2.0 mc and will have no energy at 4.0 mc. The high-frequency characteristic of the system causes little, if any, distortion to the bar.

The 0.25-μsec sin² pulse gives sensitive indications to transient distortions in the middle of the video band while the 0.125-μsec pulse is sensitive to the variations around 4.0 mc.

The British Broadcasting Corporation and the Post Office Research Department have been using this technique for a number of years and some indication of the sensitivity of the test may be obtained when it is realized that it is possible easily to detect certain forms of distortion with 0.2-db attenuation distortion and 0.02-μsec delay distortion in a 3-mc system.

In addition the methods of using the test are divided into two categories.[16] There is a procedure known as the acceptance test which is used for the complete initial adjustment of a studio or circuit and there is the routine-testing procedure which is used as a quick maintenance test or for equalizing temporary circuits to remote pickup locations.

In addition to the acceptance test procedure there has been developed a mathematical procedure using time series which permits making calculations of and obtaining answers to the aforesaid four questions, 1–4.[17] Further, a system rating factor is proposed to permit comparison of wave-form responses of different systems.

The routine-testing procedure is greatly enhanced by the wave-form corrector which permits a rapid and accurate means of equalizing a remote program circuit.[18]

Conclusions

As is true in any type of communication system when it is necessary to send more information either a wider frequency band is necessary or more stringent tolerances must be placed on the various performance requirements of the existing circuit. The latter requirement obtains in the case of the color system and is brought about by the chroma being transmitted in the high-frequency portion of the video band where small monochrome energies are to be found.

While a monochrome signal suffers less distortion when sent through a system intended for color, it certainly does not require such a transmission path to result in a perfectly usable picture.

Envelope delay, while critical at lower frequencies in monochrome, probably does not need to be so precisely controlled to 4.2 mc as it does for color. Differential phase distortion certainly is color signal degradation as is the **I** and **Q** vector relationship.

The frequency response of a monochrome system was generally maintained fairly constant so as to assure a reasonable phase characteristic rather than to avoid a loss in picture detail. Certainly no ±3% response was required in the video band to produce a good picture.

Kinescope recording placed about the most exacting demands on the gamma characteristic of a monochrome system. Gamma correctors were available to produce what was desired rather than having to redesign the whole system.

Transient studies of monochrome systems were made by different investigators but generally such studies were not directed to so precise a solution of the transient problem. It appears that one of the largest areas for future transient studies is the per-cent rating factor method. This is particularly true when one realizes that once a number has been accepted as representing "broadcast quality," any amplifier, studio, transmitter, or circuit may be judged on a purely transient basis and immediately one knows the acceptability of such equipment.

The Simple Reactor Circuit; Its Operation and Mode Transition

J. F. RINGELMAN

A. L. FENAROLI
ASSOCIATE MEMBER AIEE

METHODS for designing simple saturable-reactor magnetic amplifiers and predicting their performance on the basis of observed phenomena have been known for some time. However, the literature in the field is still lacking a complete analysis of saturable-reactor circuitry on the basis of the mechanics of operation. Ramey[1] approached the problem of saturable-reactor analysis from a novel point of view. The theory and relationships developed in his paper established a firm foundation for the understanding of the amplifier operation. This paper utilizes the volt-second approach developed by Ramey to analyze completely the simple series saturable-reactor circuit in both its transient and steady states.

The simple reactor circuit is a complex device to analyze. An analysis based upon nonideal flux current loops leads to involved mathematical expressions which tend to obscure the mechanics of operation. Similarly, an analysis considering ideal loops will also obscure the concept of operation if sine wave excitation and constant d-c control are used for forcing functions. This follows from the fact that the resulting circuit equations do not lend themselves to explicit solutions but must be solved graphically. Since it is the purpose of this paper to describe accurately the mechanics of operation of the simple reactor circuit, two simplifying ideas are utilized. First, the analysis assumes an ideal flux current loop of zero width, an infinite slope in the unsaturated region, and a zero slope in the saturated region. Second, a square-wave supply voltage is used.

The use of an ideal loop is a valid assumption in the case of simple saturable-reactor circuits because core losses usually have only second-order effects in practical circuits and are superfluous to the mechanics of operation. If ideal loops are assumed, it follows that the reactors are sensitive to volt-second integrals only, regardless of the voltage wave shapes supplied by the sources. For purposes of analysis it is advantageous to select forcing functions which will yield explicit solutions as simply as possible. The solutions thereby derived can then be applied to saturable-reactor circuits utilizing any periodic a-c exciting voltage in the power frequency range. The combination of a square-wave exciting voltage and a constant d-c control voltage will yield explicit solutions. In addition, the relative magnitude of effective control voltage to a-c excitation voltage for this particular combination is clearly defined at all times. The latter point is extremely important in determining the mode in which the circuit is operating.

The actual circuit to be analyzed is a series-connected simple reactor circuit controlled by a constant-amplitude direct voltage and supplied by an alternating voltage of square wave shape. The analysis is restricted to resistive loads and resistive control circuit impedances. The circuit operation is described for all ratios of control circuit resistance to load resistance and control voltage to supply voltage.

The analysis as presented is based upon period equations. Each half-cycle of the supply voltage is divided into two periods, a conducting and a nonconducting period. For each period, enough is known to allow for the derivation of equations for load current, control current, and voltages across the reactors. From these equations, expressions describing the transient and steady-state operation of the circuit are derived.

With the aid of the one assumption, i.e., an ideal flux current loop, and the use of a square-wave supply voltage, several important relations describing steady-state and transient operation of the circuit are derived. The relative unimportance of the supply voltage wave shape employed to the actual mechanics of operation is emphasized by some of the derived equations which are identical with those derived by Ramey, utilizing completely different forcing functions. The circuit operation in each half-cycle is shown to depend upon the operation in the previous half-cycle. The output current is shown to be transient only in respect to firing angle. Two modes of operation are shown to exist which are fundamentally different in nature. Finally, the transition from mode to mode is shown to be smooth and to depend upon circuit parameters and relative magnitudes of the source voltages present in the circuit.

List of Symbols

e_{ac} = instantaneous a-c supply voltage
e_L = instantaneous load voltage
E_{ac} = instantaneous square-wave supply voltage
$E_{L,1,avg}$ = average load voltage for first half-cycle
$E_{L,n,avg}$ = average load voltage for nth half-cycle
$E_{L,ss}$ = average steady-state load voltage
E_m = maximum value of sine wave
E_c = d-c control voltage
i_L = instantaneous load current
i_c = instantaneous control current
I_m = instantaneous magnitude of load current in conducting period (square wave)
$I_{L,n,avg}$ = average load current in nth half-cycle
I_{ss} = average steady-state load current
$I_{c,avg}$ = average control current
R_c = lumped control circuit resistance
R_L = lumped load circuit resistance
t_n = firing time in the nth half-cycle
t_{ss} = steady-state firing time
T = time duration of half-cycle
N = turns ratio (control turns)/(load turns)
n = integer number of half-cycles greater than zero

$$K=N^2\frac{R_L}{R_c}$$

$$A=\frac{E_c/N}{E_{ac}}$$

$$B=\frac{1-AK}{1+AK}$$

Analysis

The circuit under consideration is shown in Fig. 1. The control voltage E_c is a constant-amplitude direct voltage and e_{ac} is the instantaneous magnitude of, for the present, any periodic alternating voltage. All the resistances of the control and load circuits are lumped into R_c and R_L respectively. Fig. 2 illustrates the flux current loops of reactors A and B.

The general equations for the load and control circuits may be written as

$$e_{ac}=e_a+e_b+i_LR_L \tag{1}$$

$$E_c=Ne_a-Ne_b+i_cR_c \tag{2}$$

where N = (control turns)/(load turns). It is now advantageous to define the conducting and non-conducting periods of a half-cycle which depend upon the relative flux conditions of the two reactors. A

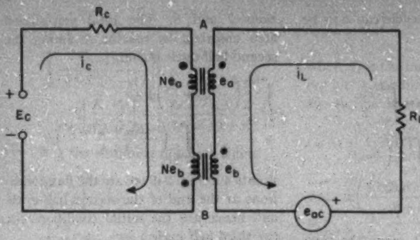

Fig. 1. Series-connected simple saturable reactor circuit

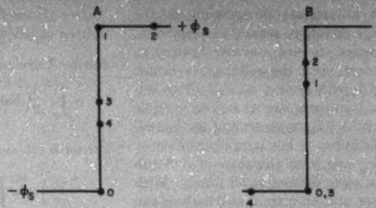

Fig. 2. Idealized flux current loops for reactors A and B

nonconducting period exists when both reactors are simultaneously unsaturated. Since ideal flux current loops have been assumed and exciting currents do not exist, control and load currents will be zero. Thus, during a period of nonconduction the general equations 1 and 2 may be reduced to the form

$$e_{ac}=e_a+e_b \qquad (3)$$

$$E_c=Ne_a-Ne_b \qquad (4)$$

Now, if one reactor saturates while the other remains unsaturated, the voltage across the saturated reactor will drop to zero. The conduction period begins at the instant of saturation of one of the reactors, allowing the other reactor to act as a transformer, and continues until both reactors are again unsaturated. Load and control currents will flow during the conduction period and, since the unsaturated reactor must still carry zero net ampere turns, $N_c i_c = N_L i_L$ or

$$i_c=\frac{i_L}{N}$$

During a conduction period when reactor *A* is saturated and reactor *B* is unsaturated, equations 1 and 2 may be reduced to

$$e_{ac}=e_b+i_L R_L \qquad (5)$$

$$E_c=-Ne_b+i_c R_c \qquad (6)$$

By making use of the relationship $i_c = i_L/N$, equations 5 and 6 may be solved for the currents

$$i_L=\frac{e_{ac}+\dfrac{E_c}{N}}{\dfrac{R_c}{N^2}+R_L} \qquad (7)$$

$$i_c=\frac{Ne_{ac}+E_c}{R_c+N^2R_L} \qquad (8)$$

Equations 7 and 8 indicate the current wave forms that can be expected for relative magnitudes of control and supply voltages. If e_{ac} is a sinusoid and E_c a constant-amplitude direct voltage, it is apparent that the amount of roundness or squareness of the current pulses is dependent upon the relative magnitudes of E_c/N and e_{ac}. In addition, the polarities of the control windings, during the conduction portion of each half-cycle, are such as to transform the supply voltage into the control circuit always in the same direction. The alternating current is thus inverted on alternate half-cycles, and a double frequency alternating current is introduced into the control circuit. This is sometimes referred to as a second harmonic. The relative content of the double frequency alternating current in the control circuit is dependent upon the relative magnitude of E_c and Ne_{ac}. Of importance is the fundamental relationship that in the conducting period the instantaneous control ampere-turns applied to the unsaturated reactor must equal the instantaneous load ampere-turns. Since, during the nonconducting period, the control and load currents are zero, the average value of control ampere-turns equals the average value of the load circuit ampere-turns for the entire half-cycle. It is not apparent, from equation 8, that the average value of the steady-state control current for the entire half-cycle is E_c/R_c. However, this is true since direct current cannot be transformed; this will be discussed later.

Thus far, the load and control currents have been described in the conducting and nonconducting periods. To define completely the circuit, it remains to consider it in its transient state. Before proceeding, it is desirable to establish initial conditions. The supply voltage is chosen to be of square wave form, and its magnitude at any instant described by E_{ac}. The flux condition for each reactor is assumed to be initially at negative saturation, point zero in Fig. 2. Referring to Fig. 3, a transient is introduced at $t=0$, at which time the supply voltage is zero and increasing positively, by the application of a control voltage E_c. Each reactor is designed to absorb one-half the volt-second area available from the supply. Solving equations 3 and 4 for e_a and e_b in the nonconducting period, reactor *A* has applied to it the voltage 1/2 $(E_{ac}+E_c/N)$ and reactor *B*, 1/2 $(E_{ac}-E_c/N)$. It is readily apparent that any voltage E_c, however small, will cause reactor *A* to saturate at some time before the end of the first positive half-cycle. The flux excursion of reactor *B*, however, is not so apparent. It is possible for reac-

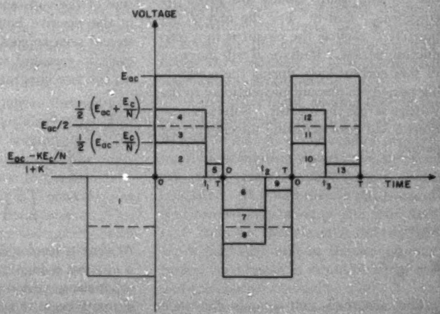

Fig. 3. Typical reactor voltages during a transient in mode 1 with K>1

tor B to saturate immediately in the negative direction, remain at point zero, or proceed toward positive saturation, dependent upon the relative magnitude of E_c/N with respect to E_{ac}. Two different transients are therefore possible with $E_c/N = E_{ac}$ representing the boundary condition. For a supply voltage of square wave form the ratio of E_c/N to E_{ac} is clearly defined at all times. With this fact utilized a transient analysis can be developed for each case. The first case to be considered is described by $E_c/N < E_{ac}$.

MODE 1: $E_c/N < E_{ac}$

If E_c/N is less than E_{ac}, reactor A will proceed toward positive saturation and saturate first at some time before the end of the first positive half-cycle. Reactor B, in the meantime, will reach some point on the unsaturated portion of its flux current loop. These conditions are illustrated by points 1 in Fig. 2.

Fig. 3 shows the reactor voltages during a transient with the circuit in mode 1 operation. At time $t = t_1$ reactor A saturates. Since each reactor is capable of absorbing one-half the volt-second area available from the supply voltage, the time t_1 is defined by

$$\int_0^T \frac{E_{ac}}{2}\,dt = \int_0^{t_1} \frac{1}{2}\left(E_{ac} + \frac{E_c}{N}\right) dt$$

where T = time duration of a half-cycle. From $t = 0$ to $t = t_1$ reactor B proceeds toward positive saturation by absorbing the volt-second integral

$$\int_0^{t_1} \frac{1}{2}\left(E_{ac} - \frac{E_c}{N}\right) dt$$

At time $t = t_1$ reactor A saturates and is effectively eliminated from the load and control circuits. Reactor B is still capable of absorbing volt-seconds and hence operates as a transformer. Control current and load current begin to flow immediately and their values are given by equations 7 and 8. For the rest of the positive half-cycle the circuit is in a conducting period. Reactor B will move on its flux current loop, during the conducting period, an amount proportional to the voltage across the reactor. Solving equations 5 and 6 for e_b during the conducting period

$$e_b = \frac{E_{ac} - KE_c/N}{1+K}$$

where

$$K = \frac{N^2 R_L}{R_c}$$

The absorbed volt-seconds for each reactor for the first half-cycle can now be written as follows:

reactor A volt-seconds

$$= \int_0^{t_1} \frac{1}{2}\left(E_{ac} + \frac{E_c}{N}\right) dt = \int_0^T \frac{E_{ac}}{2}\,dt \quad (9)$$

$$\text{reactor } B \text{ volt-seconds} = \int_0^{t_1} \frac{1}{2}\left(E_{ac} - \frac{E_c}{N}\right) dt + \int_0^{t_1} \left(\frac{E_{ac} - KE_c/N}{1+K}\right) dt \quad (10)$$

Solving equation 9 for t_1 gives the time for the first firing angle

$$t_1 = \frac{T}{1 + \dfrac{E_c}{NE_{ac}}} \quad (11)$$

At the end of the first half-cycle the reactor fluxes are at position 2 in Fig. 2 and currents have flowed during the conducting period, as given by equations 7 and 8. The initial conditions for the second or negative half-cycle are therefore established. In a similar manner, the initial conditions in each half-cycle are established by the previous half-cycle. Hence for the purpose of writing equations involving volt-second areas each half-cycle can be treated individually as starting at time $t = 0$ with its associated initial conditions.

For the second half-cycle the polarity of the supply voltage changes and both reactors are again in a position to change flux. Solving for the voltage applied to the reactor B from equations 3 and 4, e_b is found to be $-E_{ac}/2 - E_c/2N$. This voltage is equal in magnitude to the voltage applied to reactor A in the nonconducting portion of the previous half-cycle. Due to the initial conditions for the second half-cycle, reactor B requires less flux change to saturate than did reactor A in the first half-cycle. Thus reactor B will saturate at a time t_2 which will be less than t_1. The time that reactor B saturates is determined by equating the sum of the volt-second areas it absorbed in the positive half-cycle and the volt-second area applied in the negative half-cycle to zero and solving for t_2. Equating the two integrals yields

$$-\int_0^{t_2} \frac{1}{2}\left(-E_{ac} - \frac{E_c}{N}\right) dt = \int_0^{t_1} \frac{1}{2}\left(E_{ac} - \frac{E_c}{N}\right) dt + \int_{t_1}^T \left(\frac{E_{ac} - KE_c/N}{1+K}\right) dt \quad (12)$$

At time t_2 reactor B saturates, reactor A is at point 3, Fig. 2, and the circuit is in a conducting period. Load and control currents begin to flow according to equations 7 and 8. The total volt-second area absorbed by reactor A during the second half-cycle is then

$$\int_0^{t_2} \frac{1}{2}\left(-E_{ac} + \frac{E_c}{N}\right) dt + \int_{t_2}^T \left(\frac{-E_{ac} + KE_c/N}{1+K}\right) dt$$

Points 4 in Fig. 2 illustrate the flux conditions at the end of the second half-cycle and hence are the initial conditions for the third half-cycle.

For the third half-cycle reactor A will saturate at time t_3 when it absorbs a positive volt-second area equal to the negative volt-second area it absorbed in the second half-cycle. If the change is observed in the direction of flux change this can be written as

$$\int_0^{t_3} \frac{1}{2}\left(E_{ac} + \frac{E_c}{N}\right) dt = -\int_0^{t_2} \frac{1}{2}\left(-E_{ac} + \frac{E_c}{N}\right) dt - \int_{t_2}^T \left(\frac{-E_{ac} + KE_c/N}{1+K}\right) dt \quad (13)$$

If signs are cleared in equations 12 and 13, the expressions are seen to be identical. Therefore, the general expression for the nth half-cycle firing time can be written as

$$\int_0^{t_n} \frac{1}{2}\left(E_{ac} + \frac{E_c}{N}\right) dt = \int_0^{t_{n-1}} \frac{1}{2}\left(E_{ac} - \frac{E_c}{N}\right) dt + \int_{t_{n-1}}^T \left(\frac{E_{ac} - KE_c/N}{1+K}\right) dt$$

or

$$\int_0^{t_n} \frac{1}{2} E_{ac}(1+A)\,dt = \int_0^{t_{n-1}} \frac{1}{2} E_{ac}(1-A)\,dt + \int_{t_{n-1}}^T E_{ac} \frac{1-AK}{1+K}\,dt \quad (14)$$

where $A = (E_c/N)/E_{ac}$

Solving equation 14 for t_n in terms of t_{n-1} gives

$$t_n = \frac{K-1}{K+1} t_{n-1} + 2\left[\frac{1-AK}{(1+K)(1+A)}\right] T \quad (15)$$

Solving equation 15 for t_2, t_3, t_n in terms of t_1 gives

$$t_2 = \frac{K-1}{K+1} t_1 + 2\,\frac{1-AK}{(1+K)(1+A)}\,T$$

$$t_3 = \left[\frac{K-1}{K+1}\right]^2 t_1 + 2\left[\frac{K-1}{K+1}\right]^1 \times \left[\frac{1-AK}{(1+K)(1+A)}\right] T + 2\left[\frac{1-AK}{(1+K)(1+A)}\right] T$$

$$t_n=\left[\frac{K-1}{K+1}\right]^{n-1}t_1+2\left[\frac{K-1}{K+1}\right]^{n-3}\times \left[\frac{1-AK}{(1+K)(1+A)}\right]T+\ldots+ 2\left[\frac{K-1}{K+1}\right]^{n-n}\left[\frac{1-AK}{(1+K)(1+A)}\right]T$$

or, using the summing notation sigma

$$t_n=\left[\frac{K-1}{K+1}\right]^{n-1}t_1+ \sum_{p=2}^{p=n}\left[\frac{K-1}{K+1}\right]^{n-p}2T\left[\frac{1-AK}{(1+K)(1+A)}\right]$$

The second term of the expression for t_n is a geometric progression of $n-1$ terms, where n is the number of half-cycles, of the form

$$\sum_{p=2}^{p=n}\alpha r^{n-p}$$

The sum of $n-1$ terms is

$$\frac{\alpha(1-r^{n-1})}{1-r}$$

where $\alpha=2T\left[\frac{1-AK}{(1+K)(1+A)}\right]$

and $r=\frac{K-1}{K+1}$

The general expression for t_n in terms of T, utilizing equation 11 for t_1, is

$$t_n=\frac{T}{1+A}\left[\frac{K-1}{K+1}\right]^{n-1}+ \frac{2T\left[\frac{1-AK}{(1+K)(1+A)}\right]\left[1-\left(\frac{K-1}{K+1}\right)^{n-1}\right]}{1-\frac{K-1}{K+1}} \qquad (16)$$

Once the transient has ended, the circuit is in steady state and the firing angle remains constant.

$$t_n=t_{n-1}=t_{ss}$$

Making this substitution in the general expression for t_n in equation 15 yields

$$t_{ss}=\frac{1-AK}{1+A}T \qquad (17)$$

As has been pointed out, the transient which ensues, upon the application of a control voltage, concerns only the firing angle. The average value of the currents flowing are, of course, dependent upon the firing angle; however, the currents that flow are known for the entire half-cycle and merely the firing time is necessary to solve for the average current. Therefore the average current in the nth half cycle is

$$I_{L,n,\mathrm{avg}}=I_M\left[\frac{T-t_n}{T}\right]=I_M\left[1-\frac{t_n}{T}\right] \qquad (18)$$

where I_m is the magnitude of the load current in a conducting period. The average current in steady state is

$$I_{ss}=I_M\left[1-\frac{t_{ss}}{T}\right], \qquad (19)$$

Dividing $I_{L,n,\mathrm{avg}}$ by I_{ss} yields

$$\frac{I_{L,n,\mathrm{avg}}}{I_s}=\frac{1-\frac{t_n}{T}}{1-\frac{t_{ss}}{T}}$$

Now, substituting for t_n and t_{ss} from equations 16 and 17 yields

$$\frac{I_{L,n,\mathrm{avg}}}{I_{ss}} =\frac{1-\frac{1}{T}\left\{\frac{T}{1+A}\left[\frac{K-1}{K+1}\right]^{n-1}+ 2T\frac{\left[\frac{1-AK}{(1+K)(1+A)}\right]\left[1-\left(\frac{K-1}{K+1}\right)^{n-1}\right]}{1-\frac{K-1}{K+1}}\right\}}{1-\frac{1}{T}\left(\frac{1-AK}{1+A}\right)t}$$

Solving for $I_{L,n,\mathrm{avg}}$ yields

$$I_{L,n,\mathrm{avg}}=I_{ss}\left[1-\frac{K}{K+1}\left(\frac{K-1}{K+1}\right)^{n-1}\right]$$

Since the average load current is equal to N times the average control current

$I_{ss}=N\frac{E_c}{R_c}$ and

$$I_{L,n,\mathrm{avg}}=\frac{NE_c}{R_c}\left[1-\frac{K}{K+1}\left(\frac{K-1}{K+1}\right)^{n-1}\right] \qquad (20)$$

The transient for the load current is completely described by equation 20. If $I_{L,n,\mathrm{avg}}$ is made equal to $1-1/e$ and the equation solved for $n/2$, the resulting equation is identical to that derived by Ramey. It is interesting that Ramey utilized completely different forcing functions, i.e., a sine wave supply and a rectified sine wave for d-c control.

It has become apparent through the development of the transient equation for load current that the transient proceeds according to relationships of the volt-second integrals applied to the two reactors. With the aid of Fig. 3 one may now more clearly visualize the transient. This figure shows the source voltage E_{ac} with respect to reactor voltages over three half-cycles. If the circuit is that of Fig. 1 and it is again assumed that the transient is initiated by the application of E_c at the beginning of the first positive half-cycle and that both reactors are at negative saturation, the transient will progress as follows. Each reactor is capable of absorbing a volt-second area equal to 1/2 $E_{ac}T$ or area 1. The voltage across reactor A, which will saturate in the first half-cycle, is 1/2 $(E_{ac}+E_c/N)$. This reactor will saturate at time t_1 when areas 2+3+4 equal area 1. Meanwhile reactor B, in proceeding from negative saturation, absorbs area 2. At time t_1 the reactor A saturates and absorbs no more volt-seconds for the remainder of the half-cycle. Reactor B, acting as a transformer, proceeds farther toward but does not reach positive saturation by absorbing area 5.

In the first half-cycle, then, the area absorbed by reactor A is area (2+3+4); and that absorbed by reactor B is area (2+5). If K is greater than 1, area (2+5)<area (2+3+4).

In the second half-cycle, reactor B now has applied to it the voltage minus 1/2 $(E_{ac}+E_c/N)$ and will reach negative saturation at time t_2 when area (6+7+8)= area (2+5).

It follows, then, since the voltage applied to reactor A carrying it to positive saturation in the first half-cycle is of the same magnitude as that carrying reactor B in the second-half cycle back to negative saturation, t_2 will be less than t_1 and area (6+7+8)<area (2+3+4).

Also, during the second, half-cycle reactor A, in proceeding from positive saturation, will absorb area 6 from $t=0$ to $t=t_2$ and area 9 from $t=t_2$ to $t=T$. It will be assumed that the area absorbed by the reactor proceeding from saturation, reactor A, again is less than the area absorbed by the reactor which saturated or area(6+9)<area (6+7+8).

This means that, in the third half-cycle, the reactor proceeding toward saturation will begin its excursion nearer saturation than did the corresponding reactor in the second half-cycle. As a result, the firing time t_3 will be less than t_2. Since the times of firing for the second and third half-cycles were different, it is apparent that the transient is not over.

On the other hand, assume that, in the second half-cycle, area (6+9) was equal to area (6+7+8). The reactor proceeding from saturation would have absorbed the same area as the reactor which saturated. It would then begin its excursion toward saturation in the third half-cycle from the same level as did the reactor which saturated in the second half-cycle. As a result, t_3 would be equal to t_2 and the transient would be over.

In summarizing, it may be said, then,

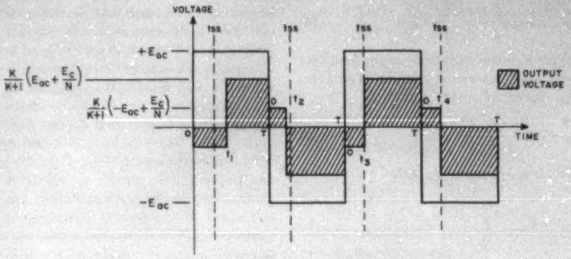

Fig. 4. Output voltage during a transient in mode 2

that in the early stages of the transient, the reactor proceeding from saturation, in a given half-cycle, will absorb fewer volt-seconds than the reactor proceeding toward saturation. As the transient progresses, this difference becomes progressively less and becomes zero when steady state is reached.

It is interesting and important to note that, once the transient has been initiated, the absolute magnitude of the reactor voltages are always identical during similar portions of time. That is, for example, in any half-cycle, a reactor proceeding toward saturation in the nonconducting period has applied to it the voltage $|1/2(E_{ac}+E_c/N)|$. It therefore follows that the average load and control currents are transient only in respect to firing time.

Mode 2: $E_c/N>E_{ac}$

To analyze the circuit for the condition $E_c/N>E_{ac}$, it is desirable to rewrite the period equations for load current, control current, and voltage across the unsaturated reactor, taking into consideration the significance of the condition $E_c/N>E_{ac}$. The circuit under consideration is again the circuit of Fig. 1. Once again initial conditions are described such that the alternating voltage has been applied and the reactors are cycling from knee to knee. At time $t=0$, each reactor is at negative saturation. E_{ac} is zero and increasing in a positive direction; see Fig. 4. Period equations will now be developed for the first four periods after the initiation of a transient $t=0$.

In mode 2 it is necessary to understand that, if a transient is initiated at time $t=0$ when reactor A and B are at negative saturation (points 0, Fig. 2), reactor B will be immediately driven further into saturation. To show this, assume that the transient is initiated an instant after $t=0$ when reactor A and B have deviated an incremental amount from negative saturation. After the instant of application of E_c, i_L, and i_c will remain zero. Equations 1 and 2 may then be solved for e_b.

$$e_b=\frac{1}{2}\left(E_{ac}-\frac{E_c}{N}\right)$$

Since, in mode 2, $E_c/N>E_{ac}$, reactor B will be driven back toward negative saturation. Thus, if the transient were started when both reactors were at negative saturation, the voltage which would tend to appear across reactor B would be in a direction to drive it further into negative saturation.

Hence, if a transient is initiated at time $t=0$ with the reactors at points 0, Fig. 2, reactor B is immediately driven further into negative saturation and the operation begins in a conducting period. Reactor B is effectively short-circuited as shown in Fig. 5(A). With the aid of this figure, the circuit equations for the first period may be written

$$E_{ac}=e_a-i_LR_L \tag{21}$$

$$E_c=Ne_a+i_cR_c \tag{22}$$

Since i_L must equal Ni_c for an unsaturated reactor, i_L may be substituted for Ni_c in equations 21 and 22. Then, solving these equations simultaneously yields

$$i_L=\frac{-E_{ac}+E_c/N}{R_L+R_c/N^2} \tag{23}$$

$$i_c=\frac{-NE_{ac}+E_c}{N^2R_L+R_c} \tag{24}$$

$$e_a=\frac{E_{ac}+KE_c/N}{1+K} \tag{25}$$

Fig. 5(A) shows the assumed direction of i_L to be opposite to that of E_{ac}. Since equation 23 shows i_L to be positive, its direction was assumed correctly. Since the voltage e_a applied to reactor A is greater than E_{ac} and since the reactor design voltage is $1/2E_{ac}$, reactor A will saturate at some time t_1 which is less than $T/2$.

The time t_1 at which reactor A reaches positive saturation is now found by setting the volt-time integral corresponding to e_a equal to 1/2 the volt-time integral of the supply voltage E_{ac} from $t=0$ to $t=T$, or

$$\int_0^{t_1}e_adt=\frac{1+AK}{1+K}\int_0^{t_1}E_{ac}dt=\int_0^T\frac{1}{2}E_{ac}dt \tag{26}$$

and solving for t_1 yields

$$t_1=\frac{1+K}{1+AK}\ \frac{T}{2} \tag{27}$$

The instant of the firing of reactor A finds reactor B also saturated.

Instantaneously, load and control currents change toward new values and, since E_{ac} is still positive and both reactors are saturated, i_c changes toward E_c/R_c and i_L becomes positive, rising toward E_{ac}/R_L. The net results of these currents are to drive reactor A farther into positive saturation and to bring reactor B out of negative saturation. After reactor B reaches the knee of its flux current loop, the voltage e_b appears across reactor B. At this time its control ampere-turns must equal its load ampere turns. Fig. 5(B) illustrates the new circuit conditions from time $t=t_1$ to $t=T$. With the aid of this figure the following can be written.

$$E_{ac}=e_b+i_LR_L \tag{28}$$

$$E_c=-Ne_b+i_cR_c \tag{29}$$

Solving for e_b yields

$$e_b=\frac{E_{ac}-KE_c/N}{1+K} \tag{30}$$

and for i_L and i_c yields

$$i_L=\frac{E_{ac}+E_c/N}{R_L+R_c/N^2} \tag{31}$$

$$i_c=\frac{NE_{ac}+E_c}{N^2R_L+R_c} \tag{32}$$

Equations 30, 31, and 32 describe e_b, i_L, and i_c respectively during the last portion of the first half-cycle from t_1 to T. During this interval of time reactor B has deviated from negative saturation by absorbing volt-seconds according to the equation

$$\int_{t_1}^Te_bdt=\frac{1-AK}{1+K}\int_{t_1}^TE_{ac}dt \tag{33}$$

At time $t=T$, the first half-cycle is completed and E_{ac} reverses polarity. At this instant the voltage e_b across reactor B changes direction and is again opposite to E_{ac}. Since E_c/N is assumed to be greater than E_{ac}, e_b is greater than E_{ac} and load current will continue to flow in the same direction. Reactor A will thus remain in positive saturation. Figure 5(C) illustrates these conditions and the following voltage and current equations may be written

$$E_{ac}=e_b-i_LR_L \tag{34}$$

$$E_c=Ne_b+i_cR_c \tag{35}$$

Solving simultaneously equations 34 and 35, making use of the relation $i_L=Ni_c$ yields

$$e_b=\frac{E_{ac}+KE_c/N}{1+K} \tag{36}$$

$$i_L=\frac{-E_{ac}+E_c/N}{R_L+R_c/N^2} \tag{37}$$

$$i_c=\frac{-NE_{ac}+E_c}{N^2R_L+R_c} \tag{38}$$

Voltage e_b from 0 to t_2 is in a direction to change the flux of reactor B back to negative saturation. Equation 33 shows the volt-second integral absorbed by reactor B, during the first half-cycle, in deviating from saturation. The time t_2 when reactor B will again saturate is found by equating this integral with the integral of e_b from $t=0$ to $t=t_2$

$$\int_0^{t_2} e_b dt=\frac{1+AK}{1+K}\int_0^{t_2} E_{ac}dt =\frac{1-AK}{1+K}\int_{t_1}^{T} E_{ac}dt \tag{39}$$

Solving equation 39 for t_2 in terms of t_1 yields

$$t_2=\frac{1-AK}{1+AK}T-\frac{1-AK}{1+AK}t_1$$

At time t_2 reactor B saturates while E_{ac} is still negative. Load current reverses polarity and flows in the direction of E_{ac}. Current i_L now drives reactor A out of saturation and again $i_L=Ni_c$. The circuit equations for Fig. 5(D) are

$$E_{ac}=e_a+i_LR_L \tag{40}$$

$$E_c=-Ne_a+i_cR_c \tag{41}$$

The circuit voltage and currents are

$$e_a=\frac{E_{ac}-KE_c/N}{1+K} \tag{42}$$

$$i_L=\frac{E_{ac}+E_c/N}{R_L+R_c/N^2} \tag{43}$$

$$i_c=\frac{NE_{ac}+E_c}{N^2R_L+R_c} \tag{44}$$

Equation 30 shows the voltage e_b applied to reactor B as it is deviating from saturation from t_1 to T. Equation 42 shows the voltage e_a applied to reactor A as it is deviating from saturation (t_2 to T). These equations show that the reactor deviating from saturation from t_n to T has the voltage applied to it

$$\frac{E_{ac}-KE_c/N}{1+K}=\frac{1-AK}{1+K}E_{ac} \tag{45}$$

Similarly, equations 25 and 36 show the voltage on the reactor proceeding toward saturation, in any half-cycle, from 0 to t_n is

$$\frac{E_{ac}+KE_c/N}{1+K}=\frac{1+AK}{1+K}E_{ac} \tag{46}$$

It may also be said that a reactor deviating from saturation in an $(n-1)$th half-cycle has a voltage across its load winding equal to

$$\frac{1-AK}{1+K}E_{ac}$$

and in the following nth half-cycle has the voltage

$$\frac{1+AK}{1+K}E_{ac}$$

Since the volt-second integrals corresponding to these two voltages must be equal, the general expression may be written

$$\frac{1-AK}{1+K}\int_{t_{n-1}}^{T} E_{ac}dt=\frac{1+AK}{1+K}\int_0^{t_n} E_{ac}dt$$

Solving for t_n in terms of t_{n-1} yields

$$t_n=\frac{1-AK}{1+AK}T-\frac{1-AK}{1+AK}t_{n-1} \tag{47}$$

From this general expression $t_2, t_3 \ldots t_n$ may be written in terms of t_1.

$$t_2=\frac{1-AK}{1+AK}T-\frac{1-AK}{1+AK}t_1$$

$$t_3=\frac{1-AK}{1+AK}T-\left[\frac{1-AK}{1+AK}\right]^2T+\left[\frac{1-AK}{1+AK}\right]^2t_1$$

$$t_4=\frac{1-AK}{1+AK}T-\left[\frac{1-AK}{1+AK}\right]^2T+\left[\frac{1-AK}{1+AK}\right]^3T-\left[\frac{1-AK}{1+AK}\right]^3t_1$$

Letting

$$\frac{1-AK}{1+AK}=B;\ t_n=(-B)^{n-1}t_1-T[(-B)^{n-1}+(-B)^{n-2}+(-B)^{n-3}+\ldots+(-B)^1]$$

$$\text{or } t_n=(-B)^{n-1}t_1-\left[\sum_{p=1}^{p=n-1}(-B)^pT\right] \tag{48}$$

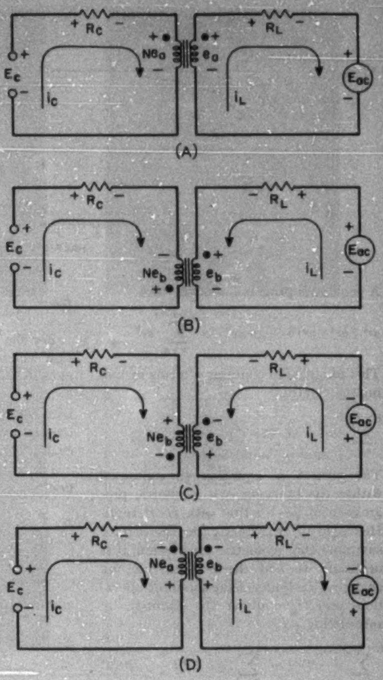

Fig. 5.

D—Circuit conditions from $t=t_2$ to $t=T$

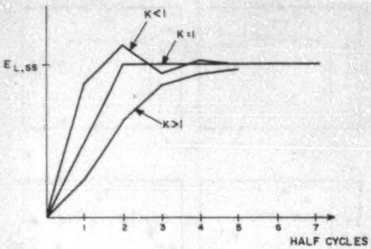

Fig. 6. Output transient responses in mode 1 operation for various values of K

A geometric progression of the form

$$ar^0+ar^1+ar^2+\ldots+ar^{n-1}=\sum_{p=0}^{p=n-1} ar^p$$

This progression contains n terms including the r^0 term.

$$\sum_{p=0}^{p=n-1} ar^p=\frac{a}{1-r}(1-r^n)$$

The portion of equation 48 contained within the brackets is a geometric progression of $n-1$ terms with no r^0 term. Hence, to apply correctly the equation for summing this geometric progression, it is necessary to add the r^0 term, i.e., by changing the limits of the summing operation, and then adjust the quantity by subtracting a T.

$$\sum_{p=1}^{p=n-1}(-B)^pT=\sum_{p=0}^{p=n-1}(-B)^pT-(-B)^0T$$

$$=\frac{T[1-(-B)^n]}{1+B}-T$$

Therefore

$$t_n=\frac{T}{2}[AK-1]\left[\left(\frac{AK-1}{AK+1}\right)^{n-1}-1\right]+\left[\frac{AK-1}{AK+1}\right]^{n-1}t_1$$

From equation 27

$$t_1=\frac{1+K}{1+AK}\,\frac{T}{2}$$

Thus

$$t_n=\left\{(1-AK)+\left[\frac{K(1+A^2K)}{AK+1}\right]\times\left[\frac{AK-1}{AK+1}\right]^{n-1}\right\}\frac{T}{2} \qquad (49)$$

The output voltage in the first half-cycle from $t=0$ to $t=t_1$ is equal to the supply voltage minus the reactor voltage, or

$$E_{ac}-\frac{1+AK}{1+K}E_{ac}$$

Similarly the output voltage in the first half-cycle from $t=t_1$ to $t=T$ can be written as

$$E_{ac}-\frac{1-AK}{1+K}E_{ac}$$

For the purpose of obtaining an equation which describes the progress of the output transient, the output voltage will be assumed to be full wave rectified. The transient equation will then describe the average output voltage over an nth half-cycle.

The average output voltage during the first half-cycle is then

$$E_{L,1,\text{avg}}=\frac{1}{T}\left[-E_{ac}\left(1-\frac{1+AK}{1+K}\right)t_1+E_{ac}\left(1-\frac{1-AK}{1+K}\right)(T-t_1)\right]$$

and in the nth half-cycle

$$E_{L,n,\text{avg}}=\frac{1}{T}\left[-E_{ac}\left(1-\frac{1+AK}{1+K}\right)t_n+E_{ac}\left(1-\frac{1-AK}{1+K}\right)(T-t_n)\right]$$

$$=\frac{E_{ac}}{T}\,\frac{K}{K+1}[-2t_n+(1+A)T] \qquad (50)$$

Substituting t_n from equation 49 into equation 50 yields

$$E_{L,n,\text{avg}}=AKE_{ac}-\frac{K^2E_{ac}(1+A^2K)}{(K+1)(AK+1)}\left[\frac{AK-1}{AK+1}\right]^{n-1} \qquad (51)$$

From equation 47

$$t_n=\frac{AK-1}{AK+1}t_{n-1}-\frac{AK-1}{AK+1}T$$

Therefore

$$t_{ss}=\frac{AK-1}{AK+1}t_{ss}-\frac{AK-1}{AK+1}T$$

$$t_{ss}=(1-AK)\frac{T}{2} \qquad (52)$$

By substituting t_{ss} for t_n in equation 50 the steady-state load voltage $E_{L,ss}$ is obtained

$$E_{L,ss}=AKE_{ac} \qquad (53)$$

The ratio of the average load voltage in the nth half-cycle to $E_{L,ss}$ is found by dividing equation 51 by equation 53

$$\frac{E_{L,n,\text{avg}}}{E_{L,ss}}=1-\frac{K(A^2K+1)}{A(K+1)(AK+1)}\left[\frac{AK-1}{AK+1}\right]^{n-1}$$

or, since

$$E_{L,ss}=AKE_{ac}=K\frac{E_c}{N}$$

$$E_{L,n,\text{avg}}=K\frac{E_c}{N}\left\{1-\frac{K(A^2K+1)}{A(K+1)(AK+1)}\times\left[\frac{AK-1}{AK+1}\right]^{n-1}\right\} \qquad (54)$$

Fig. 4 shows a typical transient for the conditions where

$K<1$

$A>1$

This figure indicates that the transient is nearly completed in three half-cycles.

Conclusions

It was previously stated that it is not obvious from the equations for the control current during the conducting period in mode 1 that the steady-state control current is E_c/R_c. It is now possible, with the relations developed in the transient analysis, to show that for any value of A, i.e., E_c/NE_{ac}, the steady-state control current is E_c/R_c. This, of course, must be true since direct voltage cannot be transformed through the reactors in steady state. If the control current for the conducting period in mode 1 is integrated from the steady-state firing time to the end of the half-cycle T and then divided by the time for the half-cycle T, the resultant current is the average control current for the half-cycle in steady state

$$I_{c,\text{avg}}=\frac{1}{T}\int_{t_{ss}}^{T}\frac{E_c+NE_{ac}}{R_c+N^2R_L}\,dt$$

$$=\frac{1}{T}\int_{\frac{1-AK}{1+A}T}^{T}\frac{E_c}{AR_c}\,\frac{1+A}{1+K}\,dt=\frac{E_c}{R_c}$$

For mode 2 the following relationship can be established

$$I_{c,\text{avg}}=\frac{1}{T}\int_0^{(1-AK)\frac{T}{2}}\frac{-NE_{ac}+E_c}{N^2R_L+R_c}\,dt+\frac{1}{T}\int_{(1-AK)\frac{T}{2}}^{T}\frac{NE_{ac}+E_c}{N^2R_L+R_c}\,dt=\frac{E_c}{R_c}$$

Hence it is seen that the voltage induced into the control circuit from the load circuit merely shapes the control current without affecting its average value. The average value of voltage in the control circuit remains E_c.

As shown in the analysis, two different transients are possible, dependent upon the relative magnitudes of E_c/N and E_{ac}. The resultant transient equations developed from these considerations are certainly different and indicate that the circuit can be capable of two modes of operation. In the analysis the mode described by $E_c/N<E_{ac}$ was called mode 1 and the mode described by $E_c/N>E_{ac}$ was called mode 2. In mode 1 the only circuit parameter which affects the transient is K, while in mode 2 the transient is a function of A and K. It is necessary to understand the significance of the two parameters A and K in order to completely understand the mechanics of operation.

The fundamental factor which determines the mode in which the circuit is operating is the factor A. If E_c/N is less than E_{ac}, the circuit is operating in mode 1; if E_c/N is greater than E_{ac}, the circuit is operating in mode 2. The question now arises as to when the circuit is capable of operating in mode 1 or mode 2. To determine this, a criterion for full output must be established.

In both modes of operation the average load ampere-turns were shown to be equal to the average control ampere-turns. In addition, the steady-state control current was shown to be E_c/R_c. Hence the average output voltage in steady state for any control voltage resulting in full output or less may be written as

$$E_{L,ss}=N\frac{E_c}{R_c}R_L=K\frac{E_c}{N}$$

When full output is reached, E_{ac} will appear across the load resistance R_L for each entire half-cycle. Thus

$$K\frac{E_c}{N}=E_{ac}$$

or $AK=1$.

From this relation it may now be seen that if $K>1$, A may not be greater than 1 before full output is reached. Thus when $K>1$, E_c/N can never be greater than E_{ac} before full output is reached and the circuit is capable of only mode 1 operation. If $K<1$, A may be increased to greater than one before full output is reached. Thus when $K<1$, the circuit may operate in either mode 1 or mode 2. It operates in mode 1 when $A<1$ and mode 2 when $A>1$.

The transient equations are of themselves quite interesting and deserving of additional considerations. For mode 1 the only circuit parameter which affects the transient is K. When K is greater than one, the circuit, after the first half-cycle, approaches steady state in an exponential manner. For $K=1$, the circuit yields steady-state output in one cycle. For a K of less than 1, keeping in mind that A must be less than 1 in order to stay in mode 1, the circuit exhibits a sort of underdamped response. It should be noted, however, that the first half-cycle produces less than the steady-state value of output. The curves of Fig. 6 illustrates the response of the circuit for various values of K in mode 1. Note that the points obtained for this curve represent average output for the corresponding half-cycle.

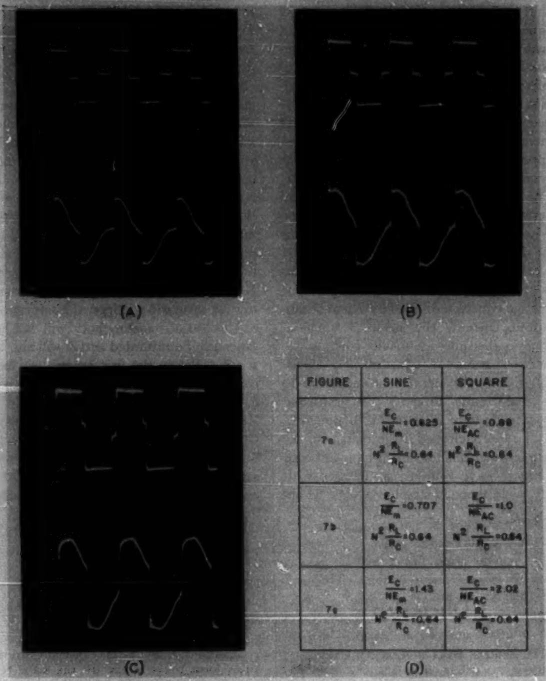

FIGURE	SINE	SQUARE

Fig. 7. Steady-state output current wave forms for typical series-connected saturable-reactor circuit for both square-wave and sine wave supply voltages

A—Output current, mode 1
B—Output current, circuit in transition from mode 1 to mode 2
C—Output current, mode 2
D—Table of circuit conditions for A, B, and C

For mode 2 the transient equation is a function of A and K. However, since AK must be less than one in order to be at less than full output, the term

$$\left(\frac{AK-1}{AK+1}\right)^{n-1}$$

for any value of output less than full output, changes sign on alternate half-cycles. Hence, for mode 2 an underdamped type of response is the only type of response possible, and once again the first half-cycle produces less than steady-state output. Fig. 4 illustrates the response of a circuit in mode 2.

Several interesting conclusions can be drawn by considering a circuit, whose parameters are such that K is less than one, operating in either mode. In mode 1 the steady-state firing time and magnitude of instantaneous output current changes as a function of E_c/N. However, a nonconducting period exists during each half-cycle and the control current is zero for the portion of the half-cycle from 0 to t_{ss}. In mode 2 it is seen from the analysis that the firing time is actually a switching time during which the output current switches between two values. No nonconducting period exists and the control current never goes to zero. The transition from mode to mode occurs when E_c/N becomes equal to E_{ac}. As E_c/N is further increased, the nonconducting period disappears and the load and control currents begin to flow over the entire half-cycle. The firing time becomes the dividing line between two distinct values of currents. When considering the transient equations for mode 1 and mode 2, it is seen that if A is made equal to one in the mode 2 transient equation 54 and the resulting output voltage equation divided by R_L to obtain output current, the mode 2 transient equation becomes identically equal to the mode 1 transient equation 20. Since equation 54 degenerates into equation 20 as A decreases to unity, the transition from mode to mode is seen to be smooth.

The approach used in the analysis of the simple series reactor circuit supplied with a square-wave voltage may be used with any wave shape of supply voltage. However, when sinusoidal excitation is used, for example, the borderline conditions between mode 1 and mode 2 are not clearly defined. For instance, the ratio E_c/Ne_{ac} changes over a half-cycle and may be greater than 1 when the sinusoid is near zero and less than 1 when e_{ac} approaches its maximum value. When the supply voltage is sinusoidal, the circuit will not operate completely in mode 2 until $E_c/N > E_m$, where $e_{ac}=E_m \sin \omega t$. Also, conditions for full output in the proportional range are not as easily described. In mode-2 operation of the circuit, conditions periodically exist when one reactor is saturated and the other is proceeding toward saturation. Upon the saturation of the second reactor, both will instantaneously be saturated and i_c will rise to E_c/R_c. Before the first reactor can become unsaturated, i_L must equal Ni_c, or $e_{ac}/R_L = NE_c/R_c$. In terms of A and K, AK must be equal to or less than unity. Otherwise, load resistance prevents sufficient load current from flowing to unsaturate the first reactor. Thus, when the control voltage is increased, decreasing the firing angle, a point is reached where, at the instant of firing, $AK=1$. Any further increase of control causes $AK>1$ at the instant of firing. The load current will thus be limited by load resistance until e_{ac} increases to make $AK=1$. When AK becomes unity, load current will again be a function of control current only. Thus proportional control will result for low values of control signal up to this boundary condition after which a control characteristic will round into full output. This condition has previously been described as resistance limiting by Storm.[2]

Fig. 7 illustrates steady-state output current wave forms for a typical series-connected saturable-reactor circuit for both square-wave and sine wave supply voltages.

◆

Discussion

H. C. Bourne, Jr. (University of California, Berkeley, Calif.): The authors have developed an interesting analysis of the series-connected saturable-reactor circuit. The use of a square-wave exciting voltage and a constant d-c control voltage serves the same purpose as the combination of a sinusoidal exciting voltage and a rectified sinusoidal control voltage. If the various sequence of states of operation remain the same, the device is responsive to half-cycle average voltages, as pointed out by the authors. Hence, it is not surprising that the results of mode-1 operation agree with those of Ramey.[1] It is even more interesting to compare the results of mode-1 operation with those obtained by Johannessen.[2] The difference equation 13 developed in this reference with appropriate changes in the symbols reads

$$E_L(n+1)=\frac{1}{N}[E_c(n+1)+E_c(n)]\times \frac{K}{1+K}+E_L(n)\frac{K-1}{K+1} \quad (55)$$

This equation describes the output in the $(n+1)$th half-cycle in terms of the control in the $(n+1)$th and the nth half-cycles and the output in the nth half-cycle. If the special conditions corresponding to equation 20 ($E_c(n)=E_c$, $n>0$ and $E_L(n)=E_c(n)=0$, $n<0$) are substituted, then

$$E_L(n+1)=\frac{1}{N}\frac{2K}{1+K}E_c+E_L(n)\frac{K-1}{K+1} n>0 \quad (56)$$

$$E_L(1)=\frac{1}{N}\frac{K}{1+K}E_c \quad (57)$$

Equations 56 and 57 may be expressed in series form to yield exactly the same results as equation 20. It appears that equation 55 contains all of the information of equation 20 and continues to give a clear picture of the dynamic operation of the circuit. Further, equation 1 is in a form amenable to immediate interpretation into a transfer function, so important from the systems viewpoint.

$$\frac{E_L(z)}{E_c(z)}=G(z)=\frac{\frac{K}{N}(z+1)}{z(K+1)-(K-1)} \text{ in which } z=e^{Ts} \quad (58)$$

With an extension of this technique the discusser has derived the difference equation describing operation in mode 2 as follows

$$E_L(n+1)=\frac{K}{N}[E_c(n+1)+E_c(n)]+\frac{K^2}{N^2E_{ac}(K+1)}[E_c^2(n+1)-E_c^2(n)]+E_L(n)\left[\frac{K}{N}\frac{E_c(n)}{E_{ac}}-1\right] \quad (59)$$

Equation 59 reduces to

$$E_L(n+1)=\frac{1}{N}\frac{2K}{AK+1}E_c+E_L(n)\frac{AK-1}{AK+1} \quad (60)$$

for a step function input and zero initial conditions. With care in determining $E_L(1)$, equation 6 gives the same result as equation 54. Because of the nonlinear character of equation 59 a simple transfer function cannot be obtained and the author's result is probably just as appropriate. However, the applicability of this technique of analysis is again illustrated.

2. Analysis of Magnetic Amplifiers by the Use of Difference Equations, P. R. Johannessen. *AIEE Transactions*, vol. 73, pt. I, 1954 (Jan. 1955 section), pp. 700–11.

J. F. Ringelman and **A. L. Fenaroli**: The authors wish to thank Dr. Bourne for his interesting discussion. Since the opportunity presents itself, we should also like to commend Mr. Johannessen on his excellent paper (reference 2 of Dr. Bourne's discussion) which introduces a more advanced technique for analyzing magnetic amplifiers.

It is certainly true that the forcing functions chosen by the authors and the forcing functions chosen by Ramey, from the analysis viewpoint, are not radically different. However, it is the authors' contention that the choice of a square-wave supply voltage in conjunction with a d-c signal voltage, aside from simplifying the mathematics involved, aids in visualizing the train of events that occur during a transient. It is also agreed that the defining difference equation as derived by Johannessen powerfully and simply describes the mechanics of operation of the device in a perfectly general sense. The primary purpose of the authors' paper is to describe the mechanics of operation of the circuit with mathematics familiar to the average engineer and, in doing so, derive realistic results and conclusions. The significance of Johannessen's difference equation is not easily appreciated by the novice in the field and it is felt that an appreciation of the period-by-period behavior of the device can best be obtained by investigating the basic nature of the transient. Once this has been firmly established the significance of Johannessen's defining difference equation becomes apparent.

Dr. Bourne is to be commended for writing the transfer function of the magnetic amplifier in a form which places magnetic amplifiers in the correct sphere of analysis. His use of Z in equation 58 suggests a sampled data system of which magnetic amplifiers are a good example. This equation, which is Johannessen's equation 15 rearranged, describes the behavior of the device in mode 1 operation.

Styroflex Aluminum-Sheathed Air-Dielectric Cable

ASSOCIATE MEMBER AIEE

STYROFLEX coaxial cable was developed to meet the demand for a uniform, low-loss cable which could be supplied in long lengths, without joints. Prior to the advent of styroflex, low attenuation in conjunction with high velocity of propagation were attainable only with rigid line or wave guide in short sections joined together.

Developed in its present form by Felten and Guilleaume in Germany,[1] styroflex cable was first introduced in the United States in 1951. Domestic manufacture was begun in 1952 at the Phelps Dodge Habirshaw Division. Extensive use in special applications has proved its versatility throughout the complete frequency spectrum up to 10,000 mc (megacycles).

Styroflex is now being employed in the United States in amplitude and frequency modulation and television broadcasts, Fig. 1; in very-high- and ultrahigh-frequency communications; and in microwave links. The Naval Research Laboratory, University of California, and Massachusetts Institute of Technology have sponsored important installations.

Outstanding properties and advantages of styroflex coaxial cable include the following:

1. Long continuous lengths on reels.
2. Excellent uniformity.
3. Low attenuation.
4. Permanent electrical properties.
5. No radiation.
6. Light weight, high strength.

Typical construction of styroflex cables is shown in Fig. 2. The inner conductor consists of either a solid copper wire or copper tube, which is coaxially supported in a homogeneous aluminum tube by the styroflex tape helix.

The extraordinary properties of styroflex tape make possible the manufacture of a uniform coaxial cable capable of permanently retaining its superior characteristics. Because of the continuous axial support, perfect centering is retained during bending and load cycling, thus assuring retention of initial properties throughout service life. The high-strength helix continuously anchors the inner conductor longitudinally with relation to the outer conductor. Pertinent electrical and physical characteristics of the styroflex line are outlined in Table I.

Manufacture

Styroflex cable is manufactured in long continuous lengths without joints and shipped on reels. A polyethylene jacket is supplied for corrosion protection when the cable is to be installed in underground ducts, directly buried, or for submarine applications.[2]

There are two basic operations in styroflex manufacture. The first operation involves the application of the tape helix on the conductor. A large number of superposed styroflex tapes form the helix. While these tapes are both narrow and thin, 0.100 by 0.005 inch for example, their high modulus of elasticity affords complete stability of the helix and permits a high order of precision in manufacture. Both diameter and pitch are continuously checked, and held to extremely close tolerances as the helical core passes through the taping machine. Styroflex cover tapes enclose the helix, forming a protective binder which enhances dielectric strength.

In the second basic operation, the aluminum sheath is applied by the drawdown or sinking method. The required length of tube, 1,000 feet maximum with present facilities, is drawn out straight from a storage reel and pressure-tested with dry gas. The helical cable core is then drawn in, and finally the tube is drawn through a lubricated sinking die to form a close-fitting sheath over the cable core. Dies are selected to give the exact tube inside diameter specified for characteristic impedance. A high-purity aluminum, 99.7 per cent, is employed as sheathing.

On larger sizes such as $3^{1}/_{8}$ inches, a temporary binding is applied over each press-stop, where local variation in stiffness of the sheath may exist. This is done in order to guard against wrinkling which might occur on subsequent reeling operations. The binding is removed after installations, except when a polyethylene jacket has been applied over it.

Every reel of styroflex must pass rigid physical and electrical factory tests. Attenuation, dielectric strength, characteristic impedance, velocity of propagation, and the voltage standing wave ratio (VSWR) are checked, as are conductivity of copper and aluminum. Each cable length is evacuated, purged, and pressure-tested with dry gas before it undergoes routine tests, and then is pressurized again before the ends are sealed for shipment.

Physical Characteristics

The styroflex cable utilizes pure copper, polystyrene, and aluminum. The tape is a unique flexible form of polystyrene, characterized by stable physical properties. No plasticizer is employed to achieve flexibility, this property being independent of temperature and obtained by special manufacturing techniques. The lack of plasticizer assures constancy of the high tensile and compressive strengths of the styroflex film; the former is over 10,000 psi (pounds per square inch), but most significant is the fact that its elongation at 10,000 psi is less than

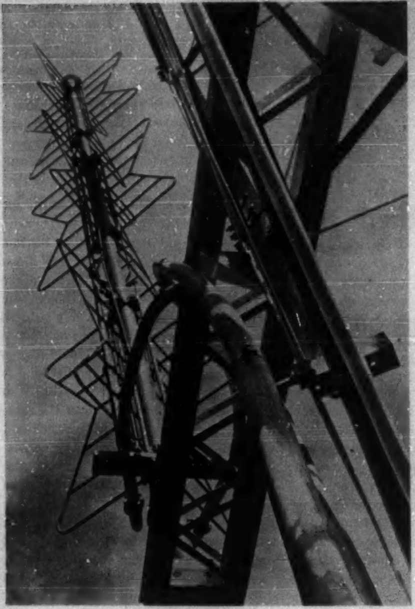

Fig. 1. Styroflex cable serving a television broadcast antenna

3 per cent. This assures complete stability of the helix. The inherent physical strength of styroflex has been demonstrated in one instance by placing a wire between cable core and aluminum sheath during the draw-down operation. Note the impressions in the wire shown in Fig. 3.

The aluminum sheath provides a naturally rugged protective covering which affords high strength and adequate flexibility. While it is recommended that field bending be guided by diameter of shipping reel drum, installed bends in the order of 10 to 15 times the cable diameter are recommended for the smaller cable sizes. However, this is not the practical limit as attested by the usual commercial practice of employing factory "formed-bend" diameters of less than half the recommended figure in the fabrication of broadcast antennas.

Styroflex cable exhibits high tensile strength. The breaking strengths of 7/8- and $3^1/_8$-inch cable were found to be 3,300 and 16,000 pounds, respectively. This is equivalent to a breaking length in the order of 6,000 feet of cable.

Many television installations which employ styroflex are supported solely by the suspension from the top of the transmitter tower, usually by means of a Kellems grip.

Hydrostatic tests to determine collapsing pressure show that standard cables can withstand pressures in the order of 1,200 psi. Hence, without reinforcement, styroflex may be employed as submarine cable to depths of several hundred feet. Service at greater depths is possible with thicker aluminum sheaths, and at very great depths, the deep-sea armored construction, Fig. 4, may be employed.

Electrical Characteristics

Styroflex cable exhibits exceptional electrical uniformity and stability. Being essentially an air-dielectric cable, it inherently exhibits lower attenuation and higher propagation velocity then do equivalent "solid" coaxials.

Its electrical characteristics may be calculated accurately from the properties of its component materials. The general high-frequency formulas (see the appendix) reliably predict cable performance up to approximately 90 per cent of TE_{10} cutoff. In the region of cutoff, a more rigorous analysis, recognizing the helical distribution of the dielectric must be followed, as shown by Griemsmann[3] in an analysis of 1/2-inch styroflex cable.

Calculated attenuation curves for the various standard sizes are given in Fig. 5.

Comprehensive studies of attenuation up to 10,000 mc have been made on 1/2-inch styroflex. Pertinent information for this cable size is tabulated in Table II. The close agreement between calculated and measured attenuation is shown in Fig. 6. The solid line indicates the calculated attenuation for 1/2-inch 50-ohm cable; the points show the record of laboratory measurements.

Initial electrical characteristics are permanent. The effect of temperature cycling upon attenuation is small, and may be estimated from the change in metal resistivities; this amounts to 1 per cent for a 10-degree-Fahrenheit temperature change.

Dielectric loss is a minor factor in the total cable attenuation. This loss is minimized by the low power factor 0.0002, low dielectric constant 2.55, and low "per-cent fill" attributable to the styroflex tape helix.

Between 10 and 100 mc, measurements of input impedance on open-circuited cable of critical length have been used to determine attenuation. Between 100 and

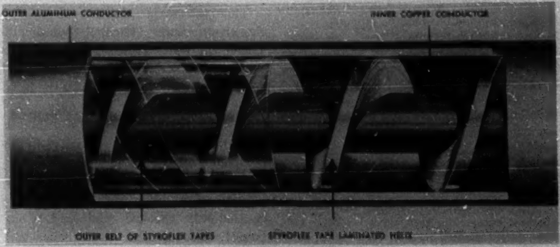

Fig. 2. Cutaway section of styroflex coaxial cable

Vol. 7
Pt. 1
1956

1,000 mc, it has been found satisfactory to employ the substitution method, which entails comparison of the cable with a calibrated attenuator. Above 1,000 mc, spurious reflections from connectors can introduce a serious source of error. In this frequency range, a slotted line in conjunction with sliding short circuit provides a most accurate method; analysis of the data plotted in polar form permits separation of the input reflection from that of the sliding short circuit. The magnitude of the short-circuit reflection is a function of the cable attenuation.

Cable uniformity has been demonstrated in several ways. Measurements of cable standing wave ratio, employing slotted line, indicate values in the order of 1.04 at 2,000 mc. The method of successive resonant frequencies is found to be sensitive for measurements in the 100-mc range. Typical measurements show VSWR les than 1.02. Variation of input impedance over a 20-mc bandwidth provides a qualitative means[4] of uniformity inspection. Fig. 7 shows two oscillograms contrasting the input impedance of styroflex with that of typical *RG* coaxial cable in the very-high-frequency region.

Power ratings have been determined on the basis of experimental heat runs, employing 60-cycle load current, made on 30-foot lengths of unjacketed cable supported horizontally in still air.

At selected temperatures of the inner conductor, ranging from 50 to 85 C (degrees centigrade), measurements of inner conductor, outer conductor, and ambient temperatures were taken, employing thermocouples; the inner conductor temperature was further checked by a resistance bridge. The majority of the tests were made on 50-ohm cable covering 1/2-7/8-, $1^5/_8$- and $3^1/_8$-inch sizes. Several cables of 70- and 77.5-ohm impedance were included. From these tests pertinent thermal transfer characteristics, applicable in this general impedance range, were established as shown in Figs. 8 and 9.

Power ratings were calculated from basic formulas (see Appendix), employing these measured thermal resistances. Independent measurements by others have shown these ratings to be accurate.

The curves of average power rating shown in Fig. 10 were developed on the basis of a maximum inner conductor temperature of 85 C, an ambient of 40 C, and a VSWR of 1.0, and apply to both 50- and 70-ohm cables. Cables having 77.5-ohm impedance are to be derated approximately 15 per cent.

The power curves apply equally to polyethylene-jacketed cables. Labora-

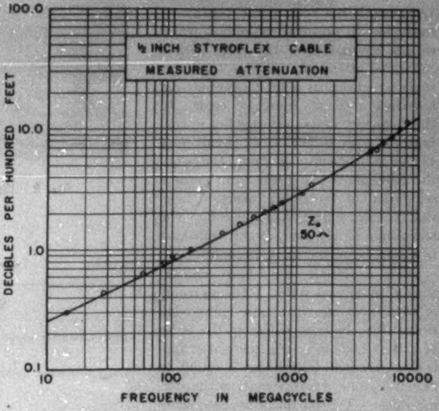

Fig. 6. Measured attenuation of 1/2-inch 50-ohm styroflex cable

tory heat runs actually show about 10-per-cent improvement in power rating due to a change from bright aluminum to black jacket.

Handling and Installation

Installation procedures for styroflex cable follow practices customary in working with lead-sheathed cable. The recommended pulling tensions and installed bending radii for styroflex are listed in Table II. When the cable is pulled during installation, bending should be limited to the drum diameter of the shipping reel. Cable flexibility is retained at low temperatures. The pulling cable may be secured to the aluminum sheath with a long Kellems grip, preferably of the double becket type.

Light braking on the reel flanges with boards usually provides ample tension to straighten cable satisfactorily through the $1^1/_8$-inch size. For larger diameters, necessary braking of the reel may be minimized by employing a simple box straightener, mounted close to the reel. A typical box length is 25 times the cable diameter. A light wipe of mineral oil on the inside of the box will help to reduce pulling tension.

Standard 2 by 8 plank is ample for the $3^1/_8$-inch cable straightener, and construction of the box with carriage bolts facilitates operations. Thus, a length of cable equal to the length of the box plus pulling grip may be straightened against a board on the ground, then swung into the opened box, the top of which is secured by bolting. The straightener may be rigged to traverse the reel as the cable is unwound. Since the box straightener described offers little braking and can be restrained with light tackle, these are relatively simple procedures; see Fig. 11.

Though some styroflex is installed in ducts or buried in the ground, much of it is aerial. The high order of self-support due to the aluminum sheath permits relatively wide spacing of trolleys and aerial suspensions. Steel-reinforced aluminum cable messenger, in conjunction with suitable aluminum lashing wire, provides adequate aerial support and maintains a neutral electrochemical aspect throughout the cable assembly.

Fittings

A complete line of fittings, proved in service, are available for interconnection of styroflex cable, and for connecting styroflex to other types of coaxial cable or equipment. Their flare-type design affords mechanical strength virtually equal to the cable.

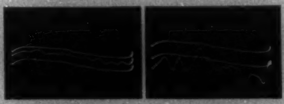

Fig. 7. Oscillograms illustrative of the greater uniformity of styroflex cable compared to RG types

A—1/2-inch 50-ohm styroflex (VSWR, 1.01)
B—Type RG-8/U (VSWR, 1.05)
Frequency band—70–90 mc (A) (B)

Applications

In service, high-frequency cables are required to maintain their electrical properties through a variety of operating conditions. They must be able to resist moisture, oxidation, and chemical attack, and must remain electrically stable under a wide range of temperature cycling. The excellent performance record of styroflex has led, inevitably, to new coaxial applications as well as to improvement in the coaxial components of many present-day systems and equipment.

Styroflex cable has been successfully employed as a radar calibration standard, wherein faithful reproduction of signal, constancy of transit time, and stability of attenuation provide the uniformity demanded of a "standard." Data transmission from remote test sites has been accomplished, efficiently, with this cable. In such capacity, its high propagation velocity and fidelity, plus availability in long reel lengths, greatly facilitates its performance and installation. Styroflex is also being employed as primary communications cable on such projects as the Defense Early Warning (DEW) line.

The continuous styroflex transmission line is particularly adapted for tower installations, both because of simplicity in handling and permanence of electrical characteristics and performance. Although $3^1/_8$-inch cable is commonly used,

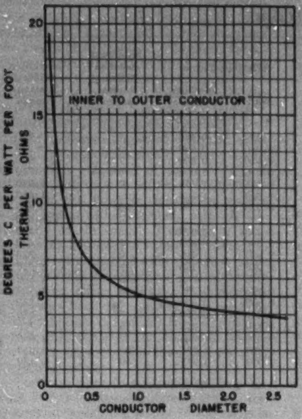

Fig. 8 (left). Thermal resistance of styroflex cable, inner conductor to outer conductor

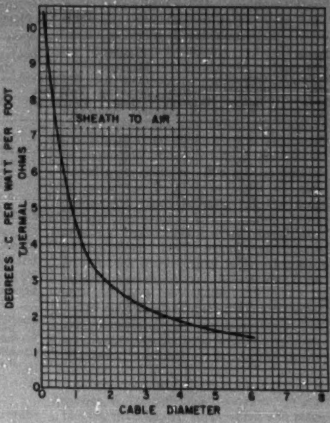

Fig. 9 (right). Thermal resistance of styroflex cable, outer conductor to air

installations of $6^1/_8$-inch styroflex have been made, the latest being the current application at station *WIIC* in Pittsburgh, Pa., where the tower rises 800 feet. This is actually the first $6^1/_8$-inch styroflex transmission line in the United States. Several similar installations are under consideration. Styroflex is also being extensively employed for antenna feed lines in scatter propagation.

Due to its broad-band uniformity, styroflex is admirably suited for multichannel long-line telephone communications. The same characteristic has led to advantageous employment in community antenna television systems where signal transmission, in some instances, embraces a 150-mc bandwidth, starting at about 50 mc. Low attenuation and permanence guarantee an efficient network cable. Absence of radiation, and stability under temperature cycling, enhance its performance. Significant economies are realized through appreciable reduction in the number of system amplifiers, and elimination of the need for cable replacement and maintenance, which justifies the use of styroflex over braided coaxial.

In general, styroflex has proved its efficiency and reliability in virtually every type of coaxial application.

Appendix I. Computation of Electrical Characteristics of Styroflex Coaxial Cable

Nomenclature

d_1 = outer diameter of inner conductor
d_2 = inner diameter of outer conductor
w = width of styroflex tape
p = lay of styroflex helix
Z_0 = characteristic impedance
k_r = dielectric constant of cable
k_s = dielectric constant of styroflex (2.55)
α_t = total attenuation in decibels per 100 feet
α_m = total metal losses in decibels per 100 feet
α_c = inner conductor loss in decibels per 100 feet
α_d = dielectric loss in decibels per 100 feet
$\tan\delta_s$ = loss tangent of styroflex (2×10^{-4})
$\tan\delta_r$ = loss tangent of cable
F_{mc} = frequency in megacycles
P = power rating in watts in still air
Δ_T = temperature rise of the inner conductor above ambient
R_{THs} = thermal resistivity between sheath and air in degrees centigrade per watt-foot
R_{THc} = thermal resistivity between inner conductor and sheath in degrees centigrade per watt-foot

Formulas

Characteristic impedance (ohms):

$$Z_0 = \frac{60}{\sqrt{k_r}} \ln\left(\frac{d_2}{d_1}\right)$$

Relative dielectric constant:

$$k_r = 1 + (k_s - 1)\frac{w}{p}\sqrt{\frac{1+p^2}{\pi 2_{d_1 d_2}}}$$

Total attenuation (decibels per 100 feet);

$$\alpha_t = \alpha_m + \alpha_d$$

Total metal loss (decibels per 100 feet);

Discussion

John W. E. Griemsmann (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): The form of this cable is of interest in that the continuous dielectric provides for broadbanding not possible with lines having spaced dielectric supports. This is advantageous when long lengths or high multiplicity of supports are required. The advantage in attenuation over solid dielectric cables is obvious and again appears important when long lengths are involved.

Analytically, any cable is subject to impedance instability resulting from minute local variations in characteristic impedance along the length of the cable. This effect, for all cables, is accentuated by long lengths and low attenuation. While a comparison of impedance stability has been made in the paper for the very-high-frequency region, a comparison of impedance uniformity with that of corresponding solid dielectric cable at higher frequencies would provide useful information. Because of the intensity of gaseous ionization possible at higher frequencies, the 60-cycle breakdown values would appear to indicate only basic electric integrity of the cable. Here again, comparison of breakdown values at radio frequencies with that of solid dielectric cable would provide useful information relating to high-power pulse applications. Important differences between styroflex and solid dielectric flexible cables are that styroflex is semiflexible and that the connector assembly job is more complex than that for solid dielectric cables.

The more rigorous analysis given in reference 3 of the paper stipulates a critical frequency at which the power in the cable is directed parallel to the helix. The values of critical frequency computed from the theory correspond approximately to values of cutoff of the first unsymmetrical mode, assuming a homogeneous dielectric and using the effective value of dielectric constant as indicated in Table III.

Table III. Values of Critical Frequency

Line Size, Inches	Critical Frequency, Kilomegacycles	Cutoff, First Unsymmetrical Mode, Kilomegacycles
3/8	14.02	15.7
1/2	11.31	11.17
7/8	6.85	6.42
$1^{1}/_{4}$	3.82	3.28

While the theory shows a calculable difference from the more elementary theory of the paper at one-half critical frequency, appreciable changes in attenuation and wave length (in cable) does not appear to take place for frequencies lower than about 90 per cent of critical frequency. Measured values of the departure of attenuation and wave length (in cable) from those given by the low-frequency values have been found to be in agreement with theory.

Tests made at microwave frequencies indicate that the recommended values of minimum bending radii will not give rise to significant additional reflections.

E. J. Merrell, A. L. McKean, and **J. Arbuthnott, Jr.:** Dr. Griemsmann's comments and suggestions are sincerely appreciated. We would like to supplement the electrical measurements given in the paper and briefly comment on some points of discussion.

Recent laboratory measurements of uniformity made over 50-mc bandwidths up to 4,000 mc show the VSWR of 1/2-inch 50-ohm styroflex to be about 1.04 at 2 kilomegacycles, 1.06 at 3 kilomegacycles, and 1.08 at 4 kilomegacycles. The measurements indicated that the sources of nonuniformity were random rather than uniformly spaced small discontinuities. Cable test lengths were 1,000 feet.

With regard to breakdown voltage of styroflex, it should be made clear that the 60-cycle test voltages listed in Table I are withstand voltages carrying a factor of safety; they are not breakdown values. Breakdown at 60 cycles may be estimated by employing a limiting voltage gradient of 70 volts per minute. This applies equally at megacycle frequencies based on continuous a-c characteristics. If the peak voltage of a pulse of high-frequency power does not exceed this gradient, breakdown will not occur. Under certain conditions, a greater peak gradient may apply, when considering shorter pulses or those having lower pulse repetition frequencies.

The semiflexible characteristic of styroflex aluminum-sheathed cable is recognized in handling, hence we have indicated that recommended installation procedures follow lead-sheathed cable practice.

Where maximum flexibility is required in service, a "styroflexible" construction employing silver-plated copper braids in place of aluminum has been made available in several smaller sizes. A polyethylene jacket is provided over all.

Styroflex connectors employ a basic flare-type design, and thus afford a permanent, sealed connection. Good electrical design in conjunction with relatively simple assembly has been achieved, so that the operation of installing connectors requires only normal skill, and follows straightforward installation procedures.

The Analytical Design and Evaluation of Electromagnets

M. J. KELLY

J. E. WALLACE
NONMEMBER AIEE

Synopsis: This paper describes a method for the accurate computation of the operating characteristics of elecromagnets, such as used in relays and other electromechanical devices. The dynamic solution involves the use of techniques applicable to digital computers. The evaluation of the computer solutions offers a means of obtaining the optimum magnet design for a given device. The method eliminates the need for building successive models for testing and evaluation.

THE DESIGN of electromagnetic devices, such as relays, has heretofore been based on empirical procedure, with the efficiency of the device largely a measure of the skill of the designer. The finished design of an electromagnet usually was the result of the construction and testing of several models. Even then it is doubtful if maximum efficiency was approached. It is the intent of this paper to describe a method whereby mathematical theory is used to reduce this cut-and-try procedure to a minimum.

Mathematical calculation of the operating characteristics of an electromagnet previously was considered extremely difficult, if not impossible, because of the large number of interdependent variables that are involved. However, by means of digital computer techniques, an analytical solution has been evolved that has given a fairly high degree of accuracy for the cases studied.

The method of solution described here requires that each variable be mathematically described as accurately as possible. By the use of difference calculus each expression may be solved individually and the results applied to the solution of the next expression. The final solution is obtained by reiterative calculation. The results of the mathematical solution will not be exact; however, they will be well within the range of the physical variables encountered in a model due to material, air gap, force, and other variations inherent in a mechanical system.

For purposes of simplification all forces are equated to act at the center of the main working air gap. This includes the inertia forces present during the dynamic portion of the operate cycle, the return spring force, and the mechanical force

The authors wish to express their appreciation to Margaret A. McCormack and Bernard M. Tostanoski of the Endicott IBM Scientific Computation Laboratory for their assistance in the application of the problem to digital computer methods.

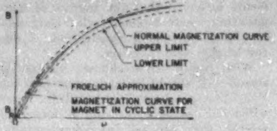

Fig. 1. Froelich approximation of magnetization curve

which may be represented by a contact load or other load.

The mathematical solution is taken in two stages. The first stage is the portion of the operate cycle required for the flux to rise to the point where sufficient magnetic force is generated to overcome the initial resistance of the mechanical system. That is the point in time at which motion is incipient. This calculation is fairly simple and may be done with a desk calculator or a slide rule. The first stage is necessary to provide the constants to be used for the dynamic solution of the second stage. The second stage involves the reiterative solution of the sequence of equations 27 to 38 and 54 to 68.

Discussion

NOMENCLATURE

Some of the variations in subscripts in the following symbols are not given here, but explained where they are used in the text.

Time Symbols

t = time, seconds (sec)
t_0 = time at which motion is incipient, sec
Δt = increment of time used for calculation of the second stage of the operation, sec

Magnetic Symbols

A = pole-face area, square inches (in.^{2})
A' = equivalent pole-face area, in.^{2}
X = length of gap at center of pole face, inches (in.)
l_t = length of iron path in magnet yoke, in.
l_c = length of iron path in magnet core, in.
l_a = length of iron path in armature, in.
l_H = length of assumed air path at hinge, in.
l_r = length of residual air gap, in.
a_t = cross-sectional area of yoke, in.^{2}
a_c = cross-sectional area of core, in.^{2}
a_a = cross-sectional area of armature, in.^{2}
a_H = cross-sectional area of hinge gap, in.^{2}
a_r = cross-sectional area of residual gap, in.^{2}
N = number of coil turns
NI = ampere-turns
$\mathcal{R}$ = reluctance, NI/maxwells
$\mathcal{R}_l$ = leakage reluctance, NI/maxwells
$\mathcal{R}_a$ = reluctance of armature, NI/maxwells
$\mathcal{R}_c$ = reluctance of core, NI/maxwells
$\mathcal{R}_t$ = reluctance of yoke, NI/maxwells
$\mathcal{R}_H$ = reluctance of hinge gap, NI/maxwells
$\mathcal{R}_r$ = reluctance of residual gap, NI/maxwells
$\mathcal{R}_o$ = closed gap reluctance except R_a, NI/maxwells
$\mathcal{R}_g$ = reluctance of magnet exclusive of leakage reluctance, NI/maxwells

$$\mathcal{R}_g=\mathcal{R}_o+\mathcal{R}_a+\frac{0.313\ X}{A'}$$

$\dfrac{0.313\ X}{A'}$ = reluctance of equivalent working gap NI/maxwells
$\mathcal{R}_t$ = total reluctance, NI/maxwells
ϕ = flux, kilomaxwells
ϕ_g = flux passing through working air gap, kilomaxwells
ϕ_l = leakage flux, kilomaxwells
ϕ_t = total flux, kilomaxwells
ϕ_r = residual flux, kilomaxwells
μ = permeability, gauss/oersteds
f = force due to magnetic pull, pounds (lbs)
B = flux density, kilomaxwells/in.^{2}
H = field intensity, NI/in.
C_1 = Froelich equation constant
C_2 = Froelich equation constant
$\mathcal{P}$ = permeance

Electrical Symbols

E = steady-state voltage, volts
I = steady-state current, amperes
e = instantaneous voltage, volts
i = instantaneous current, amperes
R = resistance, ohms
L = inductance, henry
ρ = resistivity, ohms-centimeter
ϵ = energy, joules

Mechanical Symbols

F_A = force available to accelerate armature, lbs
F = mechanical force, lbs
F_0 = equivalent mechanical force acting at the center of the pole face to start motion, lbs
P = equivalent mechanical force acting at the center of the pole face, generated due to armature motion $P=f(S)$, lbs
I' = moment of inertia, in.-lbs-sec^2
r = radius, in.
M = mass, lbs sec^2/in.
M' = equivalent mass acting at the center of the pole face, lbs sec^2/in.
S = displacement at the center of the pole face, in.
V = velocity of the armature at the center of the pole face, in./sec
K = drop-out spring rate, lbs/in.

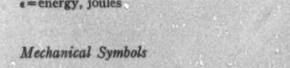

Fig. 2. Basic magnet structures

1—Two leg
2—Three leg
3—E-core

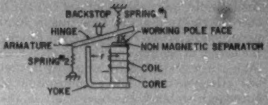

Fig. 3. Diagram of simple 2-leg magnet

Note that throughout the text the subscript o is used to denote the value of a quantity at the time (t_o) when motion is incipient; for example, X_o, ϕ_{go}, etc.

MAGNETIZATION OF MATERIALS

The problem of approximating the magnetization curve by a mathematical expression was solved by Froelich and will be used in this analysis. The Froelich equation is a hyperbolic approximation with the origin at zero. The expression is as follows:

$$B=\frac{C_1H}{C_2+H} \tag{1}$$

Fig. 1 shows the relationships discussed, from which it may be seen that the Froelich approximation is of sufficient accuracy in the usual magnet design.

MAGNET DESIGN

The types of magnet structure most frequently encountered are illustrated in Fig. 2.

Each magnet type offers certain advantages. The type of magnet selected is left to the designer's discretion. In general, the type of application, the load characteristics, and the direction of desired motion will determine the type of magnet structure to be used.

Calculations for the different magnet types differ only in detail. The 2-leg core and the E core can be equated equal and the same solution used for either unit. The 3-leg core must have a modified solution due to the unequal flux distribution in the outer legs.

METHOD OF SOLUTION

So that the nature of the problem may be understood, the simple 2-leg magnet shown in Fig. 3 and the factors which enter into its operation will be considered.

In order to arrive at a solution for the operate characteristics of the sample magnet, the initial conditions must be evaluated. The procedure is as follows:

1. The total inertia of the moving system must be evaluated and converted to the equivalent mass at the center of the pole face by means of the expression:

$$M'=\frac{I'}{r^2} \tag{2}$$

Vol. 75
Pt. 1
1956

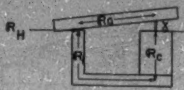

Fig. 4. Reluctances of the 2-leg magnet

$\mathcal{R}_a$ = reluctance of armature
$\mathcal{R}_c$ = reluctance of core
$\mathcal{R}_t$ = reluctance of yoke
$\mathcal{R}_H$ = reluctance of hinge
$\mathcal{R}_r$ = reluctance of residual gap
$\mathcal{R}_l$ = leakage reluctance

$\frac{0.313X}{A}$ = reluctance of working gap

2. The initial spring forces must be translated to act at the center of the pole face by taking moments. This force will be designated by F_o.

3. The force F_o is the mechanical force that must be overcome for motion to take place. Therefore, at the time motion is incipient, the magnetic force f_o must be equal to F_o; that is, at t_o, $f_o=F_o$, where t_o is the time where motion starts and is the finish of the first stage of the calculation.

$$f_o=\frac{0.0139\,\phi_{go}^2}{A} \tag{3}$$

then

$$\phi_{go}=\left(\frac{F_o\,A}{0.0139}\right)^{1/2} \tag{4}$$

This will give the value of flux ϕ_{go} required to begin motion.

4. The total reluctance of the magnetic circuit must be calculated. The reluctances of the 2-leg magnet are indicated in Fig. 4.

The following conditions apply: As reluctance of two mating metal surfaces indicates an equivalent spacing of 0.0015 to 0.002 inch, the length of the gap at the hinge end is arbitrarily taken at 0.002 inch if the armature rests on the core; and the reluctance of the core and yoke are considered to be constant at the value of ϕ_{go} derived for the particular magnet. (Care must be taken to be sure that the yoke and core operate below the knee of the magnetization curve for maximum value of flux.)

The approximate equivalent circuit for the reluctance of the 2-leg magnet is seen in Fig. 5.
Where

$$\mathcal{R}_o=\mathcal{R}_c+\mathcal{R}_t+\mathcal{R}_h+\mathcal{R}_r \text{ (assumed constant)} \tag{5}$$

$$\mathcal{R}_t=\frac{\mathcal{R}_l\left(\mathcal{R}_a+\mathcal{R}_o+\frac{0.313\,X}{A}\right)}{\mathcal{R}_l+\mathcal{R}_a+\mathcal{R}_o+\frac{0.313\,X}{A}} \tag{6}$$

As the reluctance of the iron in the circuit is a function of ϕ, the expression for R is expressed in terms of the Froelich constants and is given as follows:

$$\mathcal{R}=\frac{C_2l}{aC_1-\phi_g}\times10^{-8} \tag{7}$$

The procedure for the calculation of reluctances is as follows:

$$\mathcal{R}_H=\frac{0.313l_H}{a_H} \tag{8}$$

$$\mathcal{R}_r=\frac{0.313l_r}{a_r} \tag{9}$$

$$\mathcal{R}_c=\frac{C_2l_c}{a_cC_1-\phi_{go}}\times10^{-8} \tag{10}$$

$$\mathcal{R}_t=\frac{C_2l_1}{a_1C_1-\phi_{go}}\times10^{-8} \tag{11}$$

$$\mathcal{R}_o=\mathcal{R}_H+\mathcal{R}_r+\mathcal{R}_c+\mathcal{R}_t \tag{12}$$

$$\mathcal{R}_a=\frac{C_2l_a}{a_aC_1-\phi_{go}}\times10^{-8} \tag{13}$$

$$\mathcal{R}_g=\mathcal{R}_o+\mathcal{R}_a+\frac{0.313\,X}{A} \tag{14}$$

The leakage reluctance $\mathcal{R}_l$ is now solved.[1]
The total open gap reluctance of the magnet is

$$\mathcal{R}_t=\frac{\mathcal{R}_l\mathcal{R}_g}{\mathcal{R}_l+\mathcal{R}_g} \tag{15}$$

5. The initial inductance of the magnet may now be calculated. It will be seen from the foregoing calculations that the greater part of the total magnet reluctance resides in the working and residual air gaps. For this reason, the indutance of the magnet may be considered to be constant until the armature starts to move and the air gaps diminish.

As indicated previously the presence of residual flux in the iron and hence in the air gap, causes a slight error in the initial value of L. The following expression is used for the calculation of L_o.

$$L_o=\frac{N^2\times10^{-8}}{\mathcal{R}_t} \tag{16}$$

6. The value of current which is required to produce ϕ_{go} is:

$$i_o=\frac{\mathcal{R}_{go}\phi_{go}}{N}\times10^8 \tag{17}$$

7. The time t_o at which motion is incipient is:

$$t_o=\frac{L_o}{R}\ln\left(\frac{E}{E-Ri_o}\right) \tag{18}$$

8. This ends the calculation for the first stage of the relay operate cycle.

9. The second stage of the operate solution is accomplished by a digital computer. In addition to the previous calculations the following parameters must be defined.

The mechanical force which is developed by the motion of the armature is designated by $P=f(S)$. $f(S)$ may be any complicated force function which may be approximated by a series of spring constants multiplied by the displacement. The force P is translated by means of moments to the center of the main working air gap. For example: In the magnet shown in Fig. 3 assume spring no. *1* has a nonlinear rate and spring no. *2* has a linear rate. The resultant force at the radius r is shown by the force-displacement diagram in Fig. 6.

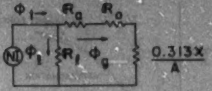

Fig. 5. Equivalent circuit of the 2-leg magnet

$P=f(S)$ may be described as follows:

$P=K_1S \quad 0<S<S_1$

$P=K_2S \quad S_1<S<S_2$

$P=K_3S \quad S_2<S<S_3$

Kn = equivalent spring rate when n = 1,2,3, etc.

If there is a sudden or gradual change in the equivalent mass of the moving system during the armature motion, the mass may be described in a similar manner.

10. It has been previously stated that the solution for the *E*-core may be obtained by the same methods as for the 2-leg core. To do this the equations for the *E*-core must be made equivalent to those of a hypothetical 2-leg core.

Consider the magnetic circuit illustrated in Fig. 7.

The leakage reluctance ($\mathcal{R}_l$) is now solved.[1]

The following relationships will hold if $a_2=a_3$

$$\mathcal{R}_t=\frac{C_2l_t}{2a_2C_1-\phi_{go}}\times10^{-8} \tag{19}$$

$$\mathcal{R}_c=\frac{C_2l_c}{a_cC_1-\phi_{go}}\times10^{-8} \tag{20}$$

$$\mathcal{R}_a=\frac{C_2l_a}{2a_aC_1-\phi_{go}}\times10^{-8} \text{ if } a_{a1}=a_{a2} \tag{21}$$

$$\mathcal{R}_r=\left(\frac{0.313\,l_{r2}}{A_2+A_3}\right)+\left(\frac{0.313\,l_{r1}}{A_1}\right) \tag{22}$$

In this expression l_{r2} is usually taken as 0.0015 to 0.002 inch depending on the degree of flatness of the mating surfaces.

l_{r1} is the length of the residual gap at the center of the working pole face.

$$\mathcal{R}_o=\mathcal{R}_t+\mathcal{R}_c+\mathcal{R}_r$$

The force developed in the magnet shown in Fig. 7 is generated in the main working gap and at the outer legs of the magnet. As the force may be directly related to the total change in reluctance in the magnet and X_1 and X_2 have a proportional relationship, an expression may be derived which relates the working gap reluctances to X_1 as illustrated in Fig. 8.

Assume $X_2=X_3$ and $A_2=A_3$

$$\mathcal{R}_{x2}=\frac{0.313X_2}{2A_2}$$

$$\mathcal{R}_{x1}=\frac{0.313X_1}{A_1}$$

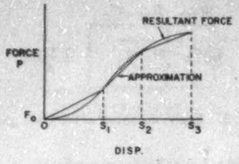

Fig. 6. Static force displacement diagram

$$\frac{X_1}{r_1}=\frac{X_2}{r_2}$$

$$X_2=\frac{r_2X_1}{r_1}$$

$$\mathcal{R}_x=\mathcal{R}_{x1}+\mathcal{R}_{x2}$$

$$=\frac{0.313X_2}{2A_2}+\frac{0.313X_1}{A_1}$$

$$=\frac{0.313\frac{r_2}{r_1}X_1}{2A_2}+\frac{0.313X_1}{A_1}$$

$$=X_1\left(\frac{0.313r_2}{2A_2r_1}+\frac{0.313}{A_1}\right)=X_1\beta$$

$$=\frac{0.313X_1}{A'}=\beta X_1$$

$$\therefore A'=\frac{0.313}{\beta}$$

where

$$\beta=\left(\frac{0.313r_2}{2A_2r_1}+\frac{0.313}{A_1}\right) \tag{23}$$

The value obtained for A' is the equivalent pole-face area and may be used in the calculations for force and reluctance. Thus

$$\mathcal{R}_g=\mathcal{R}_o+\mathcal{R}_a+\frac{0.313\,X}{A'} \tag{24}$$

$$\mathcal{R}_t=\frac{\mathcal{R}_l\mathcal{R}_g}{\mathcal{R}_l+\mathcal{R}_g} \tag{25}$$

In the expression for the value of flux (ϕ_{go}) necessary to start motion A' must be used in place of A.

$$\phi_{go}=\left(\frac{F_oA'}{0.0139}\right)^{1/2} \tag{26}$$

If these conditions of equivalence are met, the problem may be handled as the 2-leg case.

11. The solution for the 2-leg and E-core cases is completed by the reiterative calculation of the following equations in the sequence shown. The derivation of the current equation is given in the Appendix.

$$i_n=\left\{\frac{L_n-2}{L_{n-1}}\,i_{n-1}{}^2+\frac{L_oE^2}{L_{n-1}R^2}\times\right.$$

$$\left[\left(1-\epsilon^{-\frac{Rt_n}{L_o}}\right)^2-\left(1-\epsilon^{-\frac{Rt_{n-1}}{L_o}}\right)^2\right]-0.113\times$$

$$\left.\left[\frac{M'(V_{n-1}{}^2-V_{n-2}{}^2)+K(S_{n-1}{}^2-S_{n-2}{}^2)+(2F_o+P_{n-1})(S_{n-1}-S_{n-2})}{L_{n-1}}\right]\right\}^{1/2} \tag{27}$$

$$\phi_{gn}=\frac{Ni_n(10^{-8})}{\mathcal{R}_{gn-1}} \tag{28}$$

$$f_n=\frac{0.0139\phi_{gn}{}^2}{A'} \tag{29}$$

$$F_{An}=f_n-(F_o+P_{n-1}+KS_{n-1}) \tag{30}$$

$$V_n=\frac{\Delta t}{M'}\left(F_{A1}+F_{A2}+F_{A3}\ldots+\frac{F_{An}}{2}\right) \tag{31}$$

$$S_n=\Delta t\left(V_1+V_2+V_3\ldots+\frac{V_n}{2}\right) \tag{32}$$

$$P_n=f(S) \tag{33}$$

$$X_n=X_o-S_n \tag{34}$$

$$\mathcal{R}_{an}=\frac{C_2l_a}{a_ac_1-\phi_{gn}}\times10^{-8} \tag{35}$$

$$\mathcal{R}_{gn}=\mathcal{R}_{an}+\mathcal{R}_o+\frac{0.313X_{n-1}}{A'} \tag{36}$$

$$\mathcal{R}_{tn}=\frac{\mathcal{R}_l\mathcal{R}_{gn}}{\mathcal{R}_l+\mathcal{R}_{gn}} \tag{37}$$

$$L_n=\frac{N^2(10^{-8})}{\mathcal{R}_{tn}} \tag{38}$$

The problem is terminated when X=0.

3-LEG CASE

The solution for the 3-leg case is slightly more complicated than for the 2-leg and E-core cases, because the flux divides between the two outer legs in proportion to the sum of the reluctances in the parallel flux paths. By means of approximations, a solution can be obtained. Additional work is to be done to determine the degree of accuracy and possibly modify this method.

1. The mechanical forces are equated to act at the center of the main working gap as in the 2-leg case. Items 1–3, under "Method of Solution" also hold for the 3-leg case.

2. In the calculation of ϕ_{go}, the effect of the force generated at the outer leg will be small and may be ignored, therefore:

$$\phi_{go}=\left(\frac{F_o\,A'}{0.0139}\right)^{1/2} \tag{39}$$

At some point in the dynamic portion of the solution the effect of the outer working gap may become quite large and it must be taken into account in the second stage of the solution.

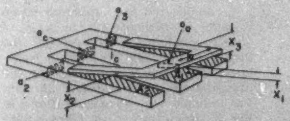

Fig. 7. Parameters of E-core magnet structure

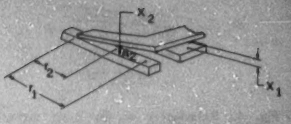

Fig. 8. Air-gap reluctance of E-core magnet

3. Once the physical parameters of the magnet have been established, it is necessary to calculate the total reluctance of the magnetic circuit as indicated in Fig. 9. The approximate equivalent circuit is shown in Fig. 10.

The following restrictions apply to the initial conditions.

1. At the time when motion starts (t_o) the armature is operating below the knee of the magnetization curve.

2. The flux in the yoke is distributed proportionately to the assumed air gap at the hinge end and the gap at the outer leg.

3. The reluctance of both legs of the magnet are assumed constant at the value calculated for the leg at the hinge end. The restrictions in this case are similar to those imposed in the 2-leg case.

4. Before the initial reluctance may be determined, values for ϕ_{10} and ϕ_{20} must be calculated. The following relationship can be shown to be a good approximation.

$$\frac{\phi_2}{\phi_1}=\frac{\frac{0.313l_h}{a_H}}{\frac{0.313(2X)}{a_2}}\text{ assuming }r_2=2r_1$$

$$\phi_2=\frac{a_2}{a_H}\left(\frac{l_H}{2X}\right)\phi_1 \tag{40}$$

Therefore, it is assumed that the flux divides proportionate to the length of the hinge and outer gap. By definition the outer gap cannot be zero so X must be limited to the value l_H.

$$\phi_{go}=\phi_{10}+\phi_{20}$$

$$=\phi_{10}+\frac{a_2}{a_H}\left(\frac{l_H}{2X_o+l_H}\right)\phi_{10}$$

$$=\phi_{10}\left[1+\frac{a_2}{a_H}\left(\frac{l_H}{2X_o+l_H}\right)\right]$$

$$K_{84}=\frac{a_2}{a_H} \tag{41}$$

$$\phi_{10}=\frac{\phi_{go}}{1+K_{84}\left(\frac{l_H}{2X_o+l_H}\right)}$$

$$\phi_{20}=\phi_{go}-\phi_{10}$$

$$\mathcal{R}_{a10}=\frac{C_2l_{a1}(10^{-8})}{C_1a_{a1}-\phi_{10}} \tag{42}$$

$$\mathcal{R}_{a20}=\frac{C_2l_{a2}(10^{-8})}{C_1a_{a2}-\phi_{20}} \tag{43}$$

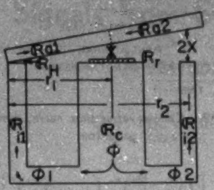

Fig. 9. Reluctances of the 3-leg magnet

$\mathcal{R}_{a1}$ = reluctance of armature (inner leg)
$\mathcal{R}_{a2}$ = reluctance of armature (outer leg)
$\mathcal{R}_{c}$ = reluctance of core
$\mathcal{R}_{i1}$ = reluctance of yoke (inner leg)
$\mathcal{R}_{i2}$ = reluctance of yoke (outer leg)
$\mathcal{R}_{H}$ = reluctance of hinge

$$\mathcal{R}_{i1}=\frac{C_2l_{i1}(10^{-8})}{C_1a_{i1}-\phi_{10}} \qquad (44)$$

$$\mathcal{R}_{i2}=\frac{C_2l_{i2}(10^{-8})}{C_1a_{i2}-\phi_{20}} \qquad (45)$$

$$\mathcal{R}_{c}=\frac{C_2l_{c}(10^{-8})}{C_1a_{c}-\phi_{go}} \qquad (46)$$

$$\mathcal{R}_{r}=\frac{0.313l_r}{a_r} \qquad (47)$$

$$\mathcal{R}_{H}=\frac{0.313l_H}{a_H} \qquad (48)$$

$\mathcal{R}_l$ is now solved.[1]

$$\mathcal{R}_{go}=\mathcal{R}_r+\mathcal{R}_c+\frac{0.313X_o}{A_1}+\left[\frac{(\mathcal{R}_{a10}+\mathcal{R}_{i1}+\mathcal{R}_H)\left(\mathcal{R}_{a20}+\mathcal{R}_{i20}+\frac{0.626X_o}{A_2}\right)}{\mathcal{R}_{a10}+\mathcal{R}_{i1}+\mathcal{R}_H+\mathcal{R}_{a20}+\mathcal{R}_{i20}+\frac{0.626X_o}{A_2})}\right] \qquad (49)$$

$$\mathcal{R}_{to}=\frac{\mathcal{R}_l\mathcal{R}_{go}}{\mathcal{R}_l+\mathcal{R}_{go}} \qquad (50)$$

$$L_o=\frac{N^2(10^{-8})}{\mathcal{R}_{to}} \qquad (51)$$

$$i_o=\frac{\mathcal{R}_{go}\phi_{go}(10^8)}{N} \qquad (52)$$

$$t_o=\frac{L}{R}\ln\left(\frac{E}{E-Ri_o}\right) \qquad (53)$$

The expression for P_n may be generated as shown in item 9 in the discussion of "Method of Solution."

The solution for the 3-leg case is completed by the reiterative calculation of the following equations in the sequence shown. The derivation of the current equation is given in the Appendix.

$$i_n=\left\{\frac{L_{n-2}}{L_{n-1}}\,i_{n-1}^2+\frac{L_oE^2}{L_{n-1}R^2}\times\right.$$

$$\left.\left[\left(1-\epsilon^{-\frac{Rt_n}{L_o}}\right)^2-\left(1-\epsilon^{-\frac{Rt_{n-1}}{L_o}}\right)^2\right]-0.113\times\left[\frac{M'(V_{n-1}^2-V_{n-2}^2)+K(S_{n-1}^2-S_{n-2}^2)+(2F_o+P_{n-1})(S_{n-1}-S_{n-2})}{L_{n-1}}\right]\right\}^{1/2} \qquad (54)$$

$$\phi_{gn}=\frac{Ni_n(10^{-8})}{\mathcal{R}_{gn-1}} \qquad (55)$$

$$\phi_{1n}=\frac{\phi_{gn}}{1+K_{34}\dfrac{l_H}{2X_n+l_H}} \qquad (56)$$

$$\phi_{2n}=\phi_{gn}-\phi_{1n} \qquad (57)$$

$$f_n=0.0139\left[\frac{\phi_{gn}^2}{A_1}+\frac{2\phi_{2n}^2}{A_2}\right] \qquad (58)$$

$$F_{An}=f_n-(F_o+P_{n-1}+KS_{n-1}) \qquad (59)$$

$$V_n=\frac{\Delta t}{M'}\left(F_{A1}+F_{A2}+F_{A3}\ldots+\frac{F_{An}}{2}\right) \qquad (60)$$

$$S_n=\Delta t\left(V_1+V_2+V_3\ldots+\frac{V_n}{2}\right) \qquad (61)$$

$$P_n=f(S_n) \qquad (62)$$

$$X_n=X_o-S_n \qquad (63)$$

$$\mathcal{R}_{a1n}=\frac{C_2l_{a1}(10^{-8})}{C_1a_{a1}-\phi_{1n}} \qquad (64)$$

$$\mathcal{R}_{a2n}=\frac{C_2l_{a2}}{C_1a_{a2}-\phi_{2n}}\times10^{-8} \qquad (65)$$

$$\mathcal{R}_{gn}=\mathcal{R}_r+\mathcal{R}_c+\frac{0.313X_n}{A}+\left[\frac{(\mathcal{R}_{a1n}+\mathcal{R}_{i1}+\mathcal{R}_H)\left(\mathcal{R}_{a2n}+\mathcal{R}_{i2}+\frac{0.626X_n}{A_2}\right)}{\mathcal{R}_{a1n}+\mathcal{R}_{i1}+\mathcal{R}_H+\mathcal{R}_{a2n}+\frac{0.626X_n}{A_2}+\mathcal{R}_{i2}}\right] \qquad (66)$$

$$\mathcal{R}_{tn}=\frac{\mathcal{R}_l\mathcal{R}_{gn}}{\mathcal{R}_l+\mathcal{R}_{gn}} \qquad (67)$$

$$L_n=\frac{N^2(10^{-8})}{\mathcal{R}_{tn}} \qquad (68)$$

The problem is terminated when $X=0$.

Summary

The results of the computations give a good approximation within the stated limits. Several sample problems have been computed and the results checked by comparison with measurements of operating models. The method has also been applied to improve the design of relay magnet structures, with excellent results.

For the first stage of the operate solution it is not necessary that the solution be obtained manually. The computer may be programmed to start at $t_o=0$.

The utility of this method is the ability to run a large number of solutions with a minimum human effort. As the parameters of the magnet are varied, the approach to the optimum operating characteristics may be analyzed and additional direction given to the design. For example, the International Business Machines Corporation Card Programmed Calculator will provide a solution in approximately 15 minutes for a magnet which requires 4 milliseconds to seal. In an 8-hour day, 32 magnet designs may be evaluated.

It should be noted that the effects of eddy currents do not appear in the solution. In some types of magnets, the eddy currents have a large effect on the operate characteristics. In these cases it would be noted that the measured current would be substantially different than the computed current even though the displacement, velocity, etc., agree quite well. It may be assumed that the greater part of this difference is due to eddy currents.

Some initial work has been started to include the effects of eddy currents, but it is not sufficiently advanced to be included in this report.

It may also be pointed out that some of the assumptions were based on rather meager data. Further investigation is necessary in this field, but it is felt that in its present state, the information in this report is a useful aid in magnet design.

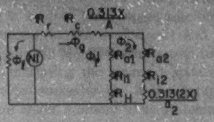

Fig. 10. Equivalent circuit of the 3-leg magnet

$\frac{0.313X}{A}$ = reluctance of center working gap

$\frac{0.313(2X)}{A_2}$ = reluctance of outer leg working gap

$\mathcal{R}_r$ = reluctance of residual
$\mathcal{R}_l$ = leakage reluctance

Appendix. Derivation of Current Equation

It has been shown that the equation for inductance is as follows:

$$L=\frac{N^2(10^{-8})}{\mathcal{R}_t}$$

In an electromagnet with the armature in an open position, it may be shown that a large portion of the total reluctance resides in the air gaps. For the moderate values

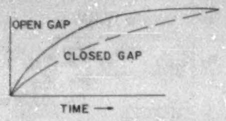

Fig. 11. Current versus time curve, static condition

of H encountered in the types of magnets under discussion the reluctance may be assumed constant for the open-air-gap case. Likewise then, the inductance may be assumed constant.

If the magnet armature is blocked closed, the foregoing is no longer the case and the reluctance is greatly reduced at low values of flux and becomes a function of the magnitude of the flux. Generally it may be assumed that the average inductance is much greater in this case.

The dynamic case, wherein the armature is allowed to operate as the current is applied, must lie somewhere between the foregoing examples.

The current rise for the case of constant inductance may be derived from the following expression:

$$L\frac{di}{dt}+Ri=E$$

thus

$$i=\frac{E}{R}\left(1-e^{-\frac{Rt}{L}}\right)$$

If the average closed gap inductance is considered, this expression will hold. The current will rise in the manner indicated in Fig. 11.

In the dynamic case the current will rise as shown in Fig. 12.

In the dynamic case the fact that L is a variable must be considered; therefore

$$L\frac{di}{dt}+Ri=E \quad L=f(\phi,i)\pm\text{constant}$$

This equation does not lend itself to solution by rigorous means, but if the energy relationships involved in the operation of the magnet are analyzed, a method of solution is suggested.

When voltage is applied to the coil of an electromagnet an energy transfer is involved. A portion of the energy is stored in the magnetic field and a portion is dissipated as heat in the I^2R loss in the magnet coil. Of the energy which has gone into the generation of the field, a portion is irreversibly lost in the hysteresis effects in the iron and in the generation of eddy currents. The remainder of the field energy may be used to do mechanical work.

If the energy transferred to the magnet with the armature blocked open is considered, total input energy

$$\epsilon=\int e\,i\,dt$$

$$=\int\left(L\frac{di}{dt}+Ri\right)idt$$

$$=\frac{1}{2}Li^2+\int Ri^2dt$$

the energy dissipated

$$\epsilon_D=\int Ri^2dt$$

the field energy

$$\epsilon_F=\frac{1}{2}Li^2$$

If no motion of the armature occurs, the inductance is assumed constant. Therefore

$$i=\frac{E}{R}\left(1-e^{-\frac{Rt}{L}}\right)$$

$$\epsilon_F=\frac{1}{2}Li^2$$

$$=\frac{1}{2}L\left(\frac{E^2}{R^2}\left(1-e^{-\frac{Rt}{L}}\right)^2\right)$$

$$=\frac{E^2L}{2R^2}\left[\left(1-e^{-\frac{Rt}{L}}\right)^2\right]$$

where

L = henrys
i = amperes
E = joules

If the armature is allowed to move as a result of the magnetic pull the mechanical energies involved are as follows:

$$\epsilon_M=\int MVdv+\int KSds+\int\left(F_o+\frac{P}{2}\right)ds$$

$$=\frac{MV^2}{2}+\frac{KS^2}{2}+\frac{(2F_o+P)}{2}S \quad \epsilon m=\text{in}-\text{lbs}$$

where

$\frac{MV^2}{2}$ = kinetic energy

$\frac{KS^2}{2}$ = energy stored in the return spring

therefore

$\frac{(2F_o+P)}{2}S$ = energy expended in the mechanical system

$$\epsilon_M=0.113\left[\frac{MV^2+KS^2+(2F_o+P)S}{2}\right]$$

The apparent change in field energy is equal to the total field energy minus mechanical energy

$$\Delta\epsilon_F=\epsilon_F-\epsilon_M$$

This may be written in difference form as follows:

$$\left.\frac{Li^2}{2}\right]_{t_{n-1}}^{t_n}=\left\{\left.\frac{L_oE^2}{2R^2}\left(1-\epsilon^{-\frac{Rt}{L_o}}\right)^2\right]_{t_{n-1}}^{t_n}-0.113\times\left[\frac{MV^2+KS^2+(2F_o+P)S}{2}\right]_{t_{n-1}}^{t_n}\right\}$$

$$\frac{L_{n-1}i_n^2-L_{n-2}i_{n-1}^2}{2}=\left\{\frac{L_oE^2}{2R^2}\times\right.$$

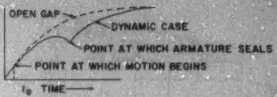

Fig. 12. Current versus time curve, dynamic condition

$$\left[\left(1-\epsilon^{-\frac{Rt_n}{L_o}}\right)^2-\left(1-\epsilon^{-\frac{Rt_{n-1}}{L_o}}\right)^2\right]-$$

$$\left.0.113\left[\frac{M(V_n^2-V_{n-1}^2)+K(S_n^2-S_{n-1}^2)+(2F_o+P_n)(S_n-S_{n-1})}{2}\right]\right\}$$

$$L_{n-1}i_n^2=\left\{L_{n-2}i_{n-1}^2+\frac{L_oE^2}{R^2}\times\right.$$

$$\left[\left(1-\epsilon^{-\frac{Rt_n}{L_o}}\right)^2-\left(1-\epsilon^{-\frac{Rt_{n-1}}{L_o}}\right)^2\right]-$$

$$\left.0.113[M(V_n^2-V_{n-1}^2)+K(S_n^2-S_{n-1}^2)+(2F_o+P_n)(S_n-S_{n-1})]\right\}$$

$$i_n^2=\left\{\frac{L_{n-2}}{L_{n-1}}i_{n-1}^2+\frac{L_oE^2}{L_{n-1}R_2}\times\right.$$

$$\left[\left(1-\epsilon^{-\frac{Rt_n}{L_o}}\right)^2-\left(1-\epsilon^{-\frac{Rt_{n-1}}{L_o}}\right)^2\right]-$$

$$\left.0.113\left[\frac{M(V_n^2-V_{n-1}^2)+K(S_n^2-S_{n-1}^2)+(2F_o+P_n)(S_n-S_{n-1})}{L_{n-1}}\right]\right\}$$

$$i_n=\left\{\frac{L_{n-2}}{L_{n-1}}i_{n-1}^2+\frac{L_oE^2}{L_{n-1}R^2}\times\right.$$

$$\left[\left(1-\epsilon^{-\frac{Rt_n}{L_o}}\right)^2-\left(1-\epsilon^{-\frac{Rt_{n-1}}{L_o}}\right)^2\right]-$$

$$\left.0.113\left[\frac{M(V_n^2-V_{n-1}^2)+K(S_n^2-S_{n-1}^2)+(2F_o+P_n)(S_n-S_{n-1})}{L_{n-1}}\right]\right\}^{1/2}$$

Signals from Switched Ferroelectric Memory Capacitors

C. F. PULVARI
NONMEMBER AIEE

G. E. McDUFFIE, JR.
NONMEMBER AIEE

CONSIDERABLE information has been published on the properties of ferroelectric materials[1-4] and their use in digital memory devices has been described.[5,6] It is the purpose of this paper to discuss the output signals from switched and unswitched ferroelectric storage capacitors, to treat the storage capacitor as a circuit element by the introduction of an equivalent circuit, and to present methods and several circuits by which the inherent signal-to-noise ratio can be improved.

The Bistable Ferroelectric Storage Element

The electrostatic hysteresis loop describes the macroscopic behavior of ferroelectrics and shows that reversibility of (remanent) polarization by an applied field is the real criterion of ferroelectric behavior. Hysteresis loops have been obtained for polycrystalline ceramics as well as for single crystals: loops for an aggregation of single crystals in a polycrystalline matrix can also be obtained. Hysteresis loops are characteristic of the material.

The hysteresis loop of a perfect single crystal is practically a rectangle. Fig. 1 shows a hysteresis curve obtained from a c-domain crystal of barium titanate at a frequency of 20 kc. After application and removal of each polarizing field, a certain remanent polarization P_r is obtained. Maximum obtainable value of P_r, or the remanent polarization, is obtained from a saturated hysteresis loop. Remanent polarization binds on the capacitor electrodes certain quantities of charge Q. If it is assumed that the remanent polarization is partially or completely changed, charge Q, corresponding to P_r, is released and may be used to obtain a signal. When a change in polarization occurs, the quantity of bound charges is altered such that during an increase in polarization, the dielectric seems to absorb charges and during a decrease in polarization, the dielectric appears to liberate charges. Thus, a ferroelectric dielectric material resembles, in some respects, a storage device; charges (electric energy) can be stored by polarizing the ferroelectric dielectric of a storage capacitor but, unlike a linear capacitor, the bound charges cannot be removed by short-circuiting the storage capacitor.

For memory applications a nearly rectangular hysteresis loop is desired; two important quantities defined by this loop are P_r, the remanent polarization, and E_c the coercive force field. E_c is defined as the field at which the polarization vanishes. In plotting P instead of D, dielectric displacement in air caused by applied field E is neglected since its value is approximately only 0.1 per cent of the remanent polarization in the case of a nearly rectangular loop.

The Bistable Capacitor as a Circuit Element

BASIC SWITCHING CIRCUIT

Fig. 2 shows the basic circuit of a single ferroelectric memory flip-flop. C_s denotes the storage capacitor; the load, which may take various forms, is symbolized by the box. R_0 is the internal resistance of the source. In order to store digital information in the storage element, a reference frame must be chosen. Assume that the $+P_r$ point on the hysteresis loop is the normal rest state of the element, and that it corresponds to a binary zero (0). A negative voltage of sufficient amplitude will switch the element from the $+P_r$ state to the $-P_r$ state; let the $-P_r$ state correspond to a binary one (1). Thus the memory elements of an array of condensers normally store binary 0's; digital words are written into the array by the application of negative write-pulses corresponding to the digital 1's present in the word.

If capacitor C_s stores a binary 1, the sensing or readout pulse causes a switching transient in the load circuit and a large signal will appear on the output terminals, indicating the binary 1 state of the selected capacitor C_s; if the storage capacitor stores a binary 0, no switching will occur and only a small elastic transient will be caused. The ratio of switched to nonswitched transient is called signal-to-noise ratio; the numerical value of this ratio will depend on the type of load used in Fig. 2 and upon the time at which the two signals are measured.

The main point in this consideration is that the storage capacitor C_s can be regarded as a transient-current source, since this is determined only by the properties of the storage capacitor such as P_r, area and thickness of the element, and its crystalline structure, provided that the internal resistance of the switching-pulse source R_0 is small.

DYNAMIC SWITCHING RESISTANCE CURVES

It has been shown that, during switching, the storage capacitor behaves like a resistance.[7] Fig. 3 shows a family of curves obtained by plotting the maximum switched current as a function of the input pulse voltage using different resistive loads. The current wave form for resistive loads is shown in Fig. 4. Dynamic switching resistance R_D is defined as the reciprocal of the slope of these curves; it is dynamic in the sense that the storage capacitor is not a steady-state device and therefore can only be measured by variations of the input voltage. From these curves the peak power supplied to the storage capacitor during switching can be determined for various resistive loads by taking the product of the maximum current and the input pulse voltage.

EQUIVALENT CIRCUIT

The family of dynamic switching resistance curves also indicates the type of equivalent circuit most suited to the storage capacitor. For a given value of input pulse voltage a variation in resistive load of approximately 1000 to 1 produces a current change of about 2 to 1, indicating an equivalent source of the current type. Once this family of curves is determined for a particular storage capacitor, an equivalent circuit can be established.

For most switching applications a convenient equivalent circuit for the bistable storage capacitor is a current generator with a resistance in parallel. When a step function is applied, the current

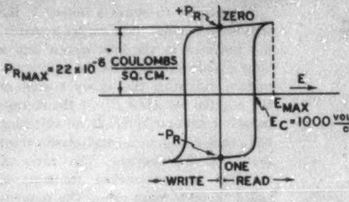

Fig. 1. Hysteresis loop of c-domain barium titanate

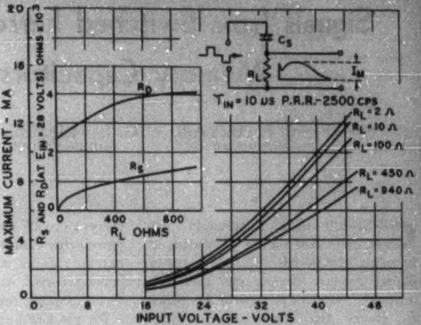

Fig. 3 (right). Dynamic switching resistance curves

generator produces a current transient as shown in Fig. 4; the elastic component of capacity C_0 can normally be neglected. From these considerations, the equivalent circuit shown in Fig. 5 can be derived where $i(t)$ designates the current generator producing a current transient; the shunt resistance, R_s, can be computed from the family of dynamic switching resistance curves, for a given applied input voltage, from the relation

$$R_s = \frac{R_L}{\frac{I_{MO}}{I_M} - 1} \tag{1}$$

where R_L is the load resistance, I_{MO} is the maximum current for $R_L = 0$, and I_M is the maximum current for the value of R_L under consideration. The inset curve in Fig. 3 shows the variation of R_D and R_S with change in load resistance. Although the ohmic value of R_S is relatively small, the ratio R_S/R_L in the range of interest is sufficiently large to justify the current source equivalent.

Different types of impedance may be applied as a load, such as a resistance, capacitance, inductance, or a nonlinear resistance of any type. Examples of such loads are resistors, capacitors, pulse transformers, and diodes or transistors. Load circuits may be formed by combining different impedances as desired. The character of the output signal depends on the type of load chosen; see Figs. 4 and 6. The load impedance may be a part of the readout circuit; different types of circuit are discussed in the following.

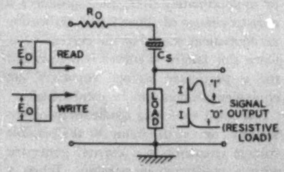

Fig. 2. Basic storage circuit

If an electronic component is to be used in circuitry for data handling or processing devices, a thorough knowledge of its switching properties is of primary interest. To facilitate mathematical treatment of related problems, a mathematical expression was developed for the switching transient.

Referring to Fig. 4, the current due to the switched charge can be approximated by

$$i(t) = \alpha I_M t e^{-\frac{t^2}{4a}} \tag{2}$$

where the maximum switching current I_M and the constant a depend on the applied switching field, and α is a constant, whose value depends on P_r and the area of the ferroelectric element; the fitting constants a and α are discussed in detail in reference 8. Equation 2 neglects the initial spike of current due to the linear component of capacity.

Illustration

As an application of this function, the output voltage due to the switching current across a parallel resistance-capacitance load has been calculated. Fig. 7(A) shows the circuits under consideration. $e(t)$ is the actual voltage developed across R_LC_L during switching; it consists of the sum of the voltage developed by the switching current $i(t)$ and the linear circuit voltage drop. A typical wave form of $e(t)$ is shown in Fig. 6. For purposes of calculation, the equivalent circuit shown in Fig. 7(B) is used; $e'(t)$ is the component of output voltage due to the switching current alone. In this example R_s, the internal shunting resistance across the current generator may be neglected if the time constant R_LC_L is chosen such that the duration of the output voltage $e'(t)$ is much larger than the duration of the current transient $i(t)$. In the case of other load impedances in which the output transient is comparable in duration to the current transient, R_s may not be neglected. Assuming the time constant R_LC_L to be such that R_s may be neglected, the equation describing behavior of the equivalent circuit is

$$\alpha I_M t e^{-\frac{t^2}{4a}} = \left(\frac{1}{R_L} + C_L \frac{d}{dt}\right) e'(t) \tag{3}$$

By considering numerical value of α, I_M and a, and neglecting numerically small terms in the exact solution of equation 3, an approximate solution can be shown to be

$$e'(t) \cong \frac{2a\alpha I_M}{C_L}\left(e^{-\frac{t}{R_LC_L}} - e^{-\frac{t^2}{4a}}\right) \tag{4}$$

Fig. 7 shows experimental and calculated values of $e'(t)$ for $C_L = 5{,}000$ micromicrofarads and $R_L = 4{,}700$ ohms. R_L was chosen at this relatively high value in order to increase the time scale so as to provide a better check on the calculated values. Typical values of the constants for small storage capacitors ($A = 10^{-2}\text{cm}^2$) are $a = 1.54 \times 10^{-12}\text{sec}^2$, $\alpha = 2.1 \times 10^6\ \text{sec}^{-1}$ and $I_m = 3 \times 10^{-3}$ amperes.

Reading Modes

To recover stored information from the ferroelectric memory element, three general methods of sensing the state of the element are possible:

1. Destructive readout.
2. Nondestructive readout.
3. Multiple readout.

Vol.
Pt. 1
1956

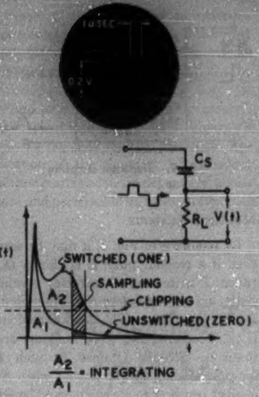

Fig. 4. Transients of a resistive load: $R_L = 220$ ohms

Destructive Readout

In destructive readout, a positive voltage is applied of sufficient amplitude to switch those memory elements in the $-P_r$ state to the $+P_r$ state. If a binary 1 is stored, switching occurs, giving rise to an output signal; if binary 0 is stored, no switching occurs and little or no output signal is obtained. Ideally, the detection of a binary 1 or 0 is a simple matter; however, when one element of an array of storage elements is sensed, the ratio of output signal for a binary 1 to the output signal for a binary 0 is well below the ideal case since the shunting capacity of the other element is appreciable.

Shunting capacity as well as series load impedance introduces a fraction of the sensing pulse, $e(t)-e'(t)$, into the output signal. The purpose of the following readout systems is to decrease or eliminate the effect of the sensing pulse and shunt capacity on the 1-to-0 output signal ratio.

Fig. 4 shows the output currents of a single storage element corresponding to a binary 1 and 0. The ratio of the two outputs can be artificially increased by decreasing or eliminating the sensing pulse through clipping, integrating, or sampling.

When clipping is used for readout, a reference level is established slightly above the amplitude of the output signal due to a binary 0. Fig. 8 shows a simple diode-clipping circuit. Since clipping may operate on a voltage produced during the actual sensing pulses, access time is very rapid.

Integrating readout compares the actual switched-to-nonswitched-charge ratio, represented by the areas A_2/A_1 in Fig. 4, rather that the ratio of current amplitudes. In this mode, a parallel resistance capacitance combination is used as the load impedance. The capacity integrates the charge while the parallel resistance acts as a discharge path. Fig. 6 shows the output signals for switched and nonswitched operation obtained across a resistance capacitance load. It may be noted that the signal does not fall to zero at the end of the pulse; thus, for complete integration, access time is inherently increased. The parallel resistance, however, may be decreased until the duration of the output signal is the same as, or less than the duration of the sensing pulse; under these conditions complete integration is not obtained. The output from the integrating circuit may be fed into a clipping circuit further to increase the switched to nonswitched ratio.

Capacity of the integrating capacitor should be sufficiently high to provide complete integration, yet it should be low enough to produce a workable signal level. It has been shown[8] that an optimum value exists which is given by

$$C_L(\text{opt}) = \frac{2AP_r}{\delta E_c} \tag{5}$$

where A is the area and δ the thickness of the element.

Sampling of the output signal may be accomplished by time sampling or by frequency sampling.

Time sampling is performed by time gating a portion of the output signal. This mode may be used on either the current wave form, as shown in Fig. 4, or on the charge wave form, as shown in Fig. 6. For ceramic storage elements of low sensitivity, it was found that time sampling of the output signal from an integrating load, during a short period immediately after the end of the sensing pulse, had certain advantages. Fig. 9 shows a simple transistor gate circuit which allows an output signal to be developed at its terminals only after the sensing pulse has dropped to zero.

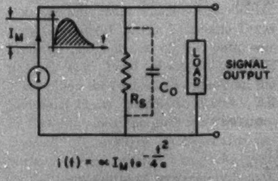

Fig. 5. Equivalent circuit

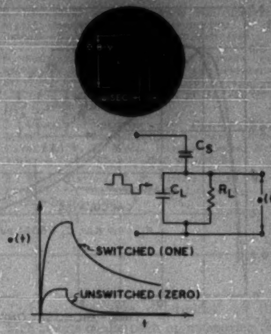

Fig. 6. Transients on a resistance-capacitance load: $R_L = 4700$ ohms, $C_L = 5{,}000$ microfarads

Frequency sampling separates the sensing pulse, developed across the load, from the integrated switched current by means of a suitable filter; it is particularly applicable when very short sensing pulses are used. This method utilizes a load whose time constant is long compared to the duration of the sensing pulse. Fig. 10 shows oscillograms of filtered and unfiltered output signals for 0.1-microsecond sensing pulses. A pulse amplifier with a relatively low-frequency cut-off (approximately 1 megacycle) was used as a filter.

Readout modes as described have been tested under varying conditions and proved satisfactory. Their characteristics and application may be summarized as follows:

1. Clipping: applicable to any type of load impedance; fast access time; requires a basic high switched-to-nonswitched ratio.
2. Integrating: capacitive-resistive load; slow access time; gives high basic switched-to-nonswitched ratio.
3. Time sampling: applicable to most types of load; medium access time; permits selection of optimum switched-to-nonswitched ratio; well suited for elements of low sensitivity.
4. Frequency sampling: applicable to most loads; medium access time; well suited for high-speed or multiple reading.

The different readout methods described may be readily combined according to need. As a practical example assume that a low-level switching transient is to be examined or utilized such as a signal from a minor loop or a signal from a material having low saturation polarization. After choosing a type of load

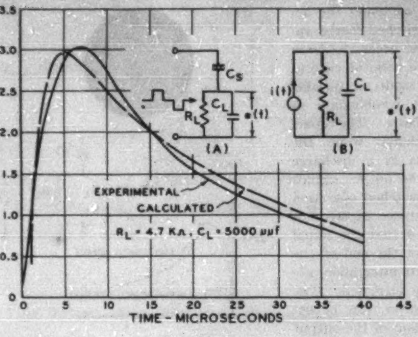

Fig. 7. Signal voltage, e'(t)

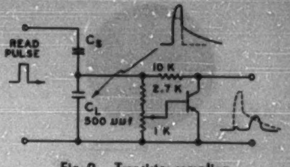

Fig. 9. Transistor sampling

suited to the desired access time, readout technique may be as follows: (1) The low level signal developed on the load is clipped to remove the sensing pulse. (2) The residual switching transient is amplified. (3) Time sampling is performed on the amplified transient such as to produce a suitable signal.

When a destructive readout mode is used and it is desired that the stored information be retained, a restoring type of operation is used. Such a readout-restore mode can be accomplished by using a feedback loop connected between output terminals of the readout circuit and the writing circuit. When a binary 1 is sensed in a memory element by a positive readout pulse, the writing circuitry is triggered, by which a negative write pulse is applied to the element thus restoring it to its original state. In this way, information in the storage elements can be "read" any desired number of times.

Nondestructive Readout

1. *Ultrasonic Mode.* Since polarized ferroelectric capacitors are inherently piezoelectric, it is possible to apply an ultrasonic field to a storage capacitor which in turn would deliver an a-c signal with the frequency of the applied ultrasonic vibrations. A stored 0 may be distinguished from a stored 1 by using a phase-sensitive output circuit connected to the load circuit, whereby a 180-degree phase difference will be observed depending on the state of the bistable capacitor. This type of readout was extensively used at the beginning and found to be practical. It was also used for detecting polarization of fine ferroelectric particles imbedded in an insulating binder; it served well for this purpose.

2. *High-Frequency Readout Modes.* Consideration was given to the use of two different high-frequency signals for energizing the rows and columns of a storage matrix but the method was not tested. In this mode nonlinearity of the storage capacitor can be used for producing a beat frequency. After rectifying, a phase-sensitive output circuit may again be used with advantage. Polarization states of the storage capacitor appear on the output with a phase difference of 180 degrees.

3. *Cross-Field Method.* In this method, two pairs of electrodes, mutually perpendicular, are applied on a single storage capacitor. One pair, applied on planes perpendicular to the *c*-axis, serve for writing, and the other, on planes perpendicular to the *a*-axis, for readout. Depending on the polarization state of the storage capacitor, the signal appears in the readout-lead with a phase difference of 180 degrees. This method was not tested.

Multiple Readout

By reference to Fig. 1, it may be seen that, if a readout pulse *E* is chosen between *E*-write and *E*-coercive, several pulses are needed before P_r pertaining to *E*-write is read out. The closer *E*-readout is to *E*-coercive, the more readouts are possible. Signals obtained in such a multiple readout will be smaller when *E*-readout is nearer to *E*-coercive and larger as their difference increases. This mode was satisfactorily tested; it may be useful in some special cases.

Although not much work has been performed on nondestructive readout systems, it was realized early in this work that in a later development it would be desirable to develop readout modes whereby stored information may be used as many times as desired.

Conclusions

In circuit applications of a bistable ferroelectric memory capacitor, it is important to determine the signal ratios for swithced and nonswitched conditions for a particular load circuit. The signal ratio represents the inherent signal-to-noise ratio for a memory capacitor. Since the attainable signal-to-noise ratio is one of the limiting factors in application, it was necessarily important that the inherent signal-to-noise ratio be improved by using additional readout circuitries.

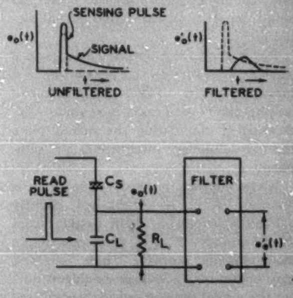

Fig. 10. Filtering circuit

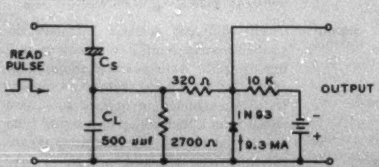

Fig. 8. Diode-clipping circuit

Inherent nonlinearity of ferroelectric storage elements prevents straightforward analysis when they are used in circuit application. It has been shown that a ferroelectric storage element may be treated as a transient current generator. The type of load used to detect binary 1's and 0's depends on the particular application of the element. The readout method employed again depends on access time and permissible signal-to-noise ratio.

THE rapidly expanding need for communications felt by United Gas Pipe Line Company indicated an examination of the new communication medium, microwave relay. Work by Bullington,[1] Crawford and Jakes,[2] Durkee,[3] Millar and Byam,[4] Thompson,[5] and others, provided valuable information for system planning and operation in most areas of the United States. In the Gulf South area, locale of the company's operations, no such information was available. Rumors, difficult to prove or disprove, were current concerning the propagation difficulties encountered by early systems in the area. In this almost subtropical section of the country, humidity variations were known to be high. Temperature inversion also had to be considered. Previous observations of very-high-frequency systems and a test at 960 mc (megacycles) indicated the possibility of unusual conditions at the higher frequencies of 2,000 and 6,700 mc.

Investigation by the Research Department of United Gas revealed the interest of the microwave manufacturers in the propagation problems of the area. A test was designed to gather data on three of the frequency bands available to pipeline companies. It was planned to operate circuits at 955.5, 1,965, and 6,730 mc over the same path for a period long enough to provide statistical data. United Gas, as the prime contractor, arranged for Philco Corporation to furnish certain equipment and services for the 6,730-mc frequencies. By separate arrangements with The Radio Corporation of America (RCA), equipment and services relating to the 955.5- and the 1,965-mc frequency were made available. The results of the ensuing test are reported in this paper. Its purpose is not to judge the relative merits of the three frequency bands involved, but rather to make the accumulated data available to the literature. It must be constantly borne in mind in the interpretation of the data presented that the tower heights and resulting path clearances were not considered optimum for any of the three frequencies being tested.

Description of Test

The test circuits were set up between the company's research laboratory at Shreveport, La., and a compressor station at Latex, Tex., a distance of 20.25 miles. A strip map of the path is shown in Fig. 1 and a profile drawn to true earth radius is shown in Fig. 2. The survey of the path was made by plotting the profile from geodetic maps which were available from Shreveport to the Louisiana-Texas border. The balance of the path was plotted from hand altimeter readings taken along the path survey line from the Louisiana-Texas border to Latex. All high points along the path were later rechecked by sensitive altimeter for accuracy. Tree covering along the path ranged from sparse to moderately heavy, principally deciduous with a few pine. Tree heights were determined on the high points of the path by measuring the height of the tallest tree in the group under consideration. No sizable streams or bodies of water were under the path. From Fig. 2 it should be noted that the path is roughly grazing at three points.

The test was conducted from May 20, 1953, through September 30, 1954. The weather for the period was generally normal except for precipitation. The month of May 1954 showed the only significant excess, with only 2 other months showing any excess. The balance of the period was so dry that the total deficiency was 17.58 inches. An average of the highest daily humidity readings which normally occur at or near sunrise showed an increase of about 3 per cent above normal. The lowest daily humidity readings usually occurring in the middle or late afternoons showed an average of about 6 per cent below normal. Temperatures for the period averaged nearly normal, with the days slightly warmer and the nights slightly cooler. Wind velocities were only slightly greater than usual with no significant variation from normal.

Fig. 3 shows the antenna installation at the Shreveport terminal. The paraboloid on the right side of the tower crossmember was illuminated by the 1,965-mc horizontally polarized dipole antenna. The paraboloid on the left was illuminated by the 955.5-mc vertically polarized dipole. The paraboloid to the left of the tower near ground level was illuminated by the 6,730-mc horizontally polarized horn-type antenna. Energy

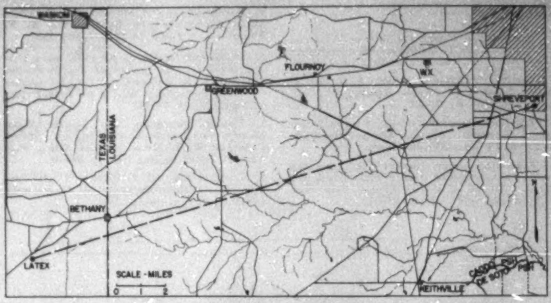

Fig. 1. Strip map of test path

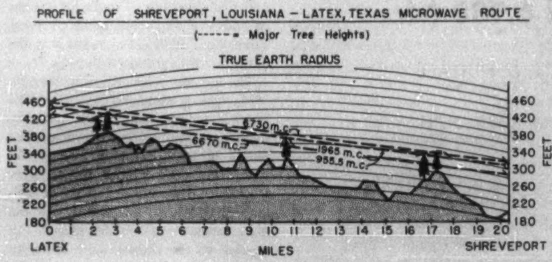

Fig. 2. Profile map of test path

was beamed from this parabola to the passive reflector at the top of the mast. The paraboloid near ground level in front of the tower and the passive reflector beneath the tower platform were part of the diversity tests not reported at this time. It is interesting to note that no significant loss differences were measured between horizontal and vertical polarization checks of the 955.5-, 1,965-, and 6,730-mc circuits. Antenna gains and circuit losses are a part of Table I. Fig. 4 is a view of the radio-equipment installation at the Shreveport terminal, showing, from left to right, the 1,965- 6,730-, and 955.5-mc radio-frequency equipment. The Latex antenna and equipment installations were similar to those at Shreveport.

The radio equipment used in the test was of standard manufacture. Since modulation was not used and bandwidth was not a consideration, the RCA equipment was adjusted where possible to increase its recording range. Modifications made to the Philco equipment did not increase the recording range over that obtainable from production equipment. Suitable arrangements were made for attaching signal recording instruments to the receiver for each test frequency.

Table I. Propagation Tests

	Circuit Frequency, Mc		
	6,730	1,965	955.5
Equipment	Philco *CLR-6*	RCA *CW-20A*	RCA *CW-5A*
Transmitter location	Latex	Latex	Latex
Transmitter power output, watts (db referred to 1 watt)	1 (0)	3 (+5)	2 (+3)
Receiver location	Shreveport	Shreveport	Shreveport
Paraboloidal antenna size, feet	6	6	4
Passive reflector size	6 by 8 feet		
Nominal antenna gains, two terminals, db	79.0	59.4	39.6
System loss for free-space transmission, db	66.3	77.0	90.8
Over-all median loss, db	80.6	92.0	105.1
Assumed obstruction loss, db	14.3	15.0	14.3

Technical Methods

The received signal level of each circuit was recorded continuously for the test period. The following information for each 15-minute period was transcribed manually from each circuit's daily chart to its daily data sheet:

1. Average loss value in decibels (db).
2. Minimum loss value in db.
3. Maximum loss value in db.
4. Number of times loss was greater than 20 db above reference value.
5. Duration of time loss was greater than 20 db above reference value, in minutes.
6. Number of times loss was greater than 30 db above reference value.
7. Duration of time loss was greater than 30 db above reference value, in minutes.
8. Number of times loss was greater than 40 db above reference value.
9. Duration of time loss was greater than 40 db above reference value, in minutes.
10. Equipment condition (one of seven symbols to denote equipment normal, under maintenance, etc.).

From the data sheets the information was punched on International Business Machines Corporation (IBM) cards, one card for each 15-minute period for each circuit. IBM machines were used for sorting and tabulating the data, but the mathematical computations and curve drawing were done by hand.

The receivers and transmitters for each circuit were calibrated as nearly as possible on a weekly basis and also before and after maintenance. All calibrations were made in db referred to one watt. Accuracy of the calibrating equipment was ±2 db. To provide a receiver calibration for a given period, a calibration curve was plotted from values averaged from the calibrations made at the beginning and end of that period. This curve was corrected to the standard transmitter output of 1 watt or 0 db by using the average transmitter power for the period as a correction factor. The corrected curve was then used to prepare a chart-reading card for transcribing the data from the charts to the data sheets.

The speed of the Esterline-Angus recording paper was chosen as 3 inches per hour as a practical maximum. For any particular chart speed, a certain minimum fade duration can be defined due to the finite width of the pen's trace. For this chart speed, a line in a downward direction followed by a return in an upward direction 1 minute later are barely separable from each other. For this reason, and because fades of shorter than 1-minute duration were expected to con-

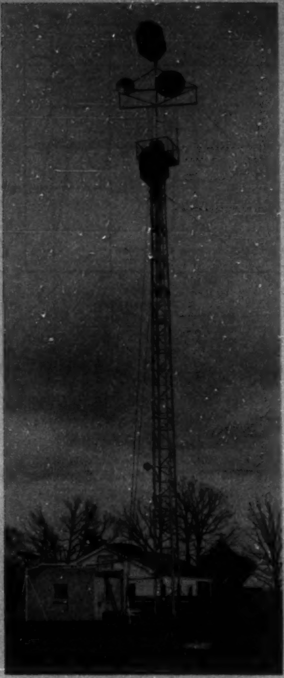

Fig. 3. Shreveport antenna installation

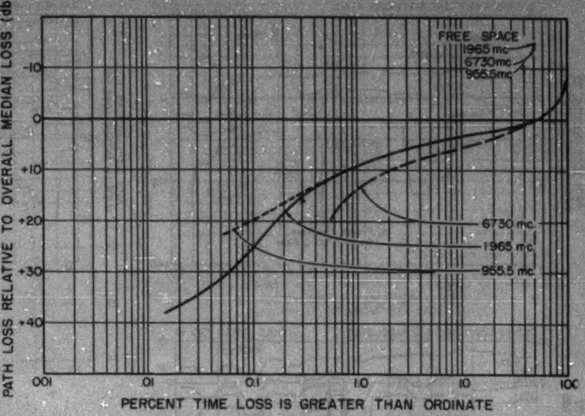

Fig. 5. 955.5-mc, 1,965-mc, and 6,730-mc loss distribution, May 20, 1953, through September 30, 1954

tribute very little to the total outage time, all fades of 1 minute or less were tabulated as 1-minute fades. It was proved later that this assumption had only a very small effect upon the over-all statistics. For example, this assumption would be expected to have the greatest effect on the statistics of the 6,730-mc circuit since these have the shortest median fade lengths [see Figs. 8(A), (B), and (C)]. From Fig. 9(A) it can be seen that only 15 per cent of the total outage time was contributed by fades of 1 minute or less duration at the +21-db level. Thus, if this total time were in error by a factor of two it would only change the total outage time for the +21-db point on the over-all distribution curve by 7.5 per cent. Consulting Fig. 5, this equivalent inaccuracy of level would make these data pessimistic by about 1 db. Similar analyses have proved none of the rest of the data to be in question by more than this 1 db.

At the start of the test it was felt that the major item of importance was the time the loss increased to fairly high values. For this reason actual integration of the outage time was set up only for losses of 20, 30, and 40 db with respect to the selected reference losses. As the test progressed, however, it was felt that following the variations of the median value and other values near it also would be necessary. It then was reasoned that since the signal variations when the signal is near the median value are usually slow, it would be acceptable to use the 15-minute average signal. Thus, as an example, the outage time for the 4-db point used was the sum of the number of cards whose average loss was greater than 4 db times 15 minutes.

Definition of Terms

"Median loss" is that loss between transmitter output and receiver input such that 50 per cent of the time the observed loss was less, and 50 per cent of the time the loss was greater. In the case of "over-all median loss," this definition applies to data for the entire test.

"System loss for free-space transmission" is the loss that would be measured between transmitter output and receiver input if the path were operated in free space without obstructions between the antennas. This loss was computed by the equipment manufacturers who used transmission-line losses measured at the test site and specification gains of the antenna systems.

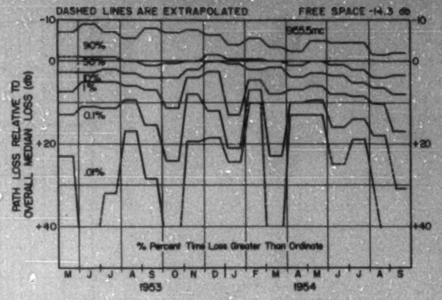
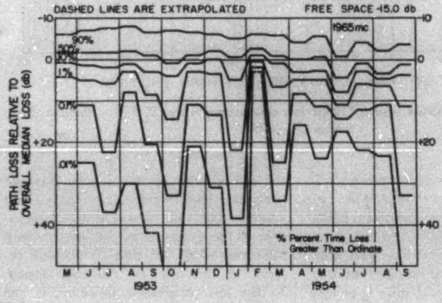
A—6,730 mc



C—955.5 mc



B—1,965 mc

Fig. 6. Seasonal probability May 20, 1953, through September 30, 1954

"Assumed obstruction loss" is the difference between over-all median loss and system loss for free-space transmission and represents the loss nominally attributed to the obstructions in the path.

Data

The primary information desired from the test was the loss distributions of the three frequencies involved operated over the same path. In setting up the test, consideration was given to providing other data such as seasonal and diurnal variations, fade-duration and faded-time distributions, rate-of-fading, and weather correlations. Since the difficulty of correlating fading and weather effects was well known, no specific and detailed effort was made in the primary phase of the test to make such correlations. A Weather Bureau station located on the path provided a source of weather data already punched on IBM cards on an hourly basis (Weather Bureau *WBAN-1* cards). With the test data also on IBM cards, it is expected that this aspect of the test will be completed as time permits.

Loss Distribution Curves

The curve shown in Fig. 5 is perhaps of the greatest significance. In this curve the loss distributions for the three frequencies are shown. In general, it shows that as the frequency increases, the amount of time the loss is greater than a selected value increases. It must be cautioned, however, that data from this figure should not be used alone to judge the relative quality of the different frequencies as regards their use in microwave relay systems or their use in different geographical areas. Other items which must be considered include antenna gain, transmission-line or wave-guide loss, radio-frequency output availability, and attainable receiver noise figures.

Seasonal Probability Curves

In the early phases of the test it was hoped that the seasonal variations noted, Figs. 6(A), (B), and (C), could be correlated with seasonal changes in K, the effective earth's radius, since K does vary on a rather periodic basis. Computations of the expected variation in signal were made assuming grazing smooth sphere diffraction. These computations predicted that the greatest losses would be present in February and the least in August. The calculated difference between the February and August median losses was 1.0 db for the 955.5-mc circuit, 1.4 db for the 1,965-mc circuit, and 2.3 db for the 6,730-mc circuit. It can be seen from inspecting the data that seasonal effects of a random nature are present to such a degree that even if the calculated effect were present, it would take many years of data to enable its extraction from the random data. For example, both the summers of 1953 and 1954 were covered by this test, but the mean signals of the summers were quite different, as shown in the median losses.

It can be noted, however, that the variation in median loss from one month to the next increases as the frequency increases. This accords with theoretical expectations that a given change in path obstruction height will cause an increasing change in the value of the received signal as the frequency becomes higher.

B—1,965 mc; May 20, 1953, through Sept. 30, 1954

Fig. 9. Faded-time distribution

Diurnal Probability Curves

In Fig. 7, loss distributions collected into 4-hour diurnal blocks are presented. From these it can be seen that the most favorable part of the day (for minimum faded time) is in the afternoon; also, it can be seen that the most unfavorable time is in the 4-hour interval between midnight and 4 a.m. Presumably the afternoon is most favorable because, on an average day, the sun has been warming the earth for some time. This causes vertical turbulence which does not support stratification. Conversely, during the early morning hours winds and atmospheric turbulence tend to be low and stratification is much more liable to cause fading.

An additional observation is that the median loss on all circuits was found to be lowest near midnight. The probable explanation of this is as follows: On a typical night the evening starts with the ground relatively warm from the sun's radiation. As night falls, the ground radiates its heat energy into space, becoming cooler; however, the higher atmosphere does not do this. Therefore, a layer of air in immediate contact with the ground becomes cooler than the air above it and thus has a dielectric constant higher than that of the air above by a definite amount. This causes the effective radius of the earth (K) to become larger and, in a grazing path such as this, causes the signal levels to rise. This effect was noticed on many evenings to a marked degree.

Fade-Duration and Faded-Time Distribution

Two informative types of presentation of the observed fades which occurred during the test are the fade-duration distribution curves, Fig. 8, and the faded-time distribution curves, Fig. 9. It should be pointed out that in Figs. 8(A) and 9(A) the period of time covered is not the entire test period.

Subjective Observations

One of the important subjective observations made during the course of this test was that it takes a great deal of information to describe accurately the statistics of even one specific propagation path. This was illustrated by several occurrences. First, the summer of 1953 was observed to have rather different characteristics as regards median loss and type of fading than the summer of 1954. Second, the substandard fades were infrequent but due to their great length had a sizable effect upon the over-all statistics. For example, in the entire 16 months of the test there were only six fades of 30 minutes or longer duration for the 1,965-mc channel at the −18-db level. These fades, however, contributed 52 per cent of the total faded time at that level. Six is hardly an adequate statistical sample, which illustrates the length of time needed to obtain accurate data, especially on the long-duration substandard fades.

Conclusions

On the basis of the data taken during this test, the loss is greater than a given value relative to median loss for a larger percentage of time as frequency increases. In general, fades become more frequent but shorter in duration as the frequency increases. It can be seen that grazing paths of the type tested suffer a sizable obstruction loss, in this case 14 to 15 db. The 1,965-mc data have been compared for a 4-month period with other propagation data taken on 2,000 mc on paths of similar length in the same locale, but with adequate clearance to insure their median signals being near the free-space value. This comparison revealed that the grazing path was 30 db or more below free-space value three times longer than the clear path, and 40 db or more nearly five times longer. Caution should be used in considering the actual value of the reliability advantage. A comparison of the circuit outage time for the two hops showed the time advantage on the clear path to be approximately 3 hours for the 4-month period. This advantage was purchased for nearly three times the antenna cost. Land required for guying would cost about four times as much and the tower itself twice as much. A complete economic evaluation of the cost of additional propagation reliability is required to ascertain its actual value for any particular hop or system.

The importance of good propagation reliability for systems using telemetering, remote control, and supervisory functions, is apparent from an examination of the diurnal curves which show that periods of maximum loss occur during the periods of greatest need for control functions. It should be emphasized again that, in addition to the important factor of propagation reliability, other factors such as antenna gain, transmission-line loss, and economic aspects must be considered in the design of a system.

Telephone Carrier Frequency Networks

G. D. WALLENSTEIN
NONMEMBER AIEE

THE GROWTH of carrier systems in the United States may be likened to the growth of the country's highways. Highways originally were built between the outskirts of cities to cope with the intercity traffic; so were carrier systems. When he traveled through a city, a motorist had to leave the highway and become submerged in local traffic until he could make connection to the next highway heading out of the city. Likewise, if carrier channels were to pass through a city, they had to become local voice drops first before they could be reinserted into another carrier system and passed on to the next city.

Highway engineers now not only build superhighways between cities, but also provide by-passes and through-connections by way of interchanges. The same can now be done with carrier systems, with interconnections and dropouts to suit the traffic. It is done with 45-class carrier networks.

Voice Channel Networks

In telephony, the ability to establish electrical connection between any two telephone instruments is the basic commodity-of-value to the subscriber. From local networks for a privileged few, the industry has grown to the point where global interconnection is taken for granted. In 1954, about 96 per cent of the world's registered telephones were potentially able to be connected one to another.

In general, such connections between any two of 90 million stations are random in character, unscheduled, and of temporary duration. This means that the connection has to be flexible and anonymous and that common standards must be employed in all participating telephone systems. Three basic features are required to accomplish these objectives.

1. Any two telephones must be able to form a working bridge for talker and listener, regardless of the instrument's origin and of the type of speech employed.

2. Telephone companies must provide some means of subscriber identification and of calling the selected party.

3. Local, regional, and national networks must have points of connection for the interchange of electric energy representing the intelligence to be transmitted.

During the first 40-odd years of telephony, telephone transmission relied on the use of direct voice frequencies as contained in speech. It confined itself to translating the acoustical energy into equivalent electrical phenomena and vice versa. Networks permitting connection between subscribers were required to handle and recognize these voice frequencies. Difficulties in maintaining standards of intelligibility over long and multisection connections, however, led to the need for definition of transmission requirements. Thus it is now possible to refer to the voice channel as a unit of information exchange upon which all telephone connection schemes are based.

It is noteworthy that discussion is still active regarding the minimum requirements for the voice channel although an international committee, Comité Consultatif International Telephonique (CCIF), founded in 1923, has deliberated on such questions for about 30 years. Nevertheless, within some margins of latitude on actual circuit quality, it is now standard practice to request and deliver voice channels fit for interconnection between a great number of separately controlled telephone companies. So much has the voice channel become an accepted

Paper 56-783, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956. Manuscript submitted March 26, 1956; made available for printing April 30, 1956.

G. D. Wallenstein is with the Lenkurt Electric Company, San Carlos, Calif.

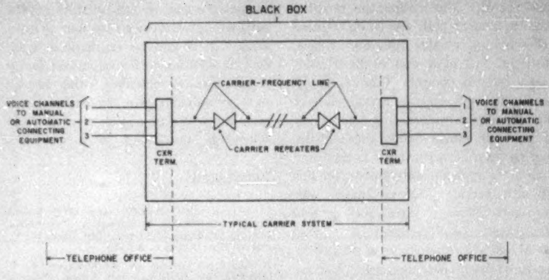

Fig. 1. The "black-box concept" applied to conventional carrier system applications

traffic unit that even the historically earlier telegraph transmission, now primarily conducted by modulation of alternating frequencies, is handled in channel increments which will conveniently fit into the capabilities of one voice channel at a time.

With basic agreement on the characteristics of the voice channel, and equipped with tools which make transmission practical over any desired distance (amplifiers, properly transposed open-wire lines, loaded cables, overseas radio), telephony came to a realization of unlimited interconnection in the late 1920's. The carrier frequencies then entered the picture. Today, in the United States alone, there are about 37 million circuit-miles of carrier telephone circuits, and the growth in this field is such that a saturation point is nowhere in sight.

The voice channel standard alone is no longer adequate for interconnection as wires and radio waves carry a multitude of speech messages encoded in arbitrary frequencies. How carrier frequencies can be standardized and integrated into interconnected network is the subject of this paper.

The Carrier-Frequency Telephone Plant

Carrier systems made their first appearance in the 1920's and have grown in use until the maxim that, "carrier is king," coined in 1949, is nearly literal truth.[1] In Europe, the CCIF has labored over problems of standardizing carrier system characteristics since the end of World War II, with participation from all parts of the world. Yet, even today, new carrier systems are being developed for specific telephone companies or for peculiar transmission conditions with little thought for network connections. It will be necessary to review the role of carrier in the telephone plant before an appraisal of network application can be made.

The entrance of carrier into telephony may be likened to other technological advances in communications. Just as the first engine on an old-fashioned coach produced literally a "horseless" carriage, so did carrier at first mean no more than "frequency-translated voice channels." With this concept, the desired end-result is still the same voice channel which, during its course of transmission, is subjected to arbitrary changes to allow a better utilization of the transmitting medium. The familiar "black-box" concept applies to everything contained between the two end-terminal positions of the voice channel. This principle is illustrated in Fig. 1.

A carrier system so applied provides for a simultaneous number of voice channels to connect two specific locations. With some types of carrier systems, each channel may be carried to a different location along the same route, as shown in Fig. 2. In either case, the job is completed at the voice channel terminal point. If connection requires, such a voice channel terminal may be switched or patched to another similar terminal, carrier-derived or physical-type.

With connection requirements applicable at the voice channel terminals only, there is no restriction on the particular *modus operandi* of the carrier system. This freedom has led to a multitude of approaches to carrier system operation. There exist today 4-wire and 2-wire carrier systems, single-side-band and some double-side-band types, systems with 3-, 4-, 5-, 6-, 8-, and 12-kc spacing between channels, systems which change direction of transmission in the same spectrum where others transmit only in one direction, etc. Lack of agreement on performance requirements for voice channels has further infiltrated carrier system design by permitting a wide range of quality both with respect to reproduction of frequencies and freedom from unwanted interference.

Fortunately there has been a growing tendency for voluntary regulation in the United States and Canada. Spearheaded by the American Association of Railroads and aided by the Bell System's very large interest in uniformity, there have been on record for some years now recommended frequency assignments for carrier systems.[2] Similar work is being done in Europe by the CCIF.[3] Such regulation has made it possible for many different carrier systems to exist on adjacent wires of the same pole line or cable. The requirement that carrier systems connect to each other at other than voice frequencies has only been applied to so-called backbone or international circuits.

Telephone companies are now adding toll channel facilities in increments of 4, 12, or more channels at one time. The

toll network is becoming such a mesh of direct, alternate routes and cross-connections that carrier systems are no longer laid out to provide end-traffic between two final points. At numerous points of connection, some of the channels combined in a given carrier system may branch off and others may terminate locally, while the remainder may go on to a more distant point served by another carrier system in a similar fashion. Such situations can be handled, of course, by provision of separate carrier systems for each section between drop-off or branching points, and connection of the voice-channels back-to-back, one at a time, as required (see Fig. 3). This has been the most common practice outside the backbone toll routes; however, it has severe technical and economical disadvantages.

From a technical standpoint, every voice-frequency connection between carrier systems repeats the carrier-modulation procedure and thus adds to the number of times the frequency accuracy and range of the derived voice channels may be affected, as illustrated in Figs. 4 and 5. Economically, the major cost factor in carrier systems is the equipment associated with the channelizing process (modulation and filtering), and the attendant expense in office mounting space, power, and maintenance. If carrier systems can be so constructed that the channelizing elements may be omitted, their direct through-connections can be made for bands of carrier frequencies which carry a number of voice channels and more than 50 per cent of the cost can usually be saved. The connection diagram of Fig. 4 would then appear greatly simplified as shown in Fig. 6.

For carrier systems to become suitable for network layout without resorting to conventional voice frequencies, three requirements must be met:

1. The channel end and the carrier-frequency transmission equipment must be separable.
2. Specific increments of channels must be recognized as group units at standardized frequencies.
3. All commonly encountered transmission media must qualify for system application.

Such requirements amount to a master plan for telephone transmission networks which is comparable to other fundamentals such as the common railroad gauge which permits the same car to travel from one end of North America to the other. It is not surprising, therefore, that until recently this concept had only been adopted in two limited cases: in the United States, by the American Telephone and Telegraph Company for backbone circuits served by the *J/K/L* carrier systems; and in Europe, on selected international toll circuits under CCIF recommendations.[4]

In the United States, advantage was

taken of one centralized common control over the development, application, and operation of these carrier systems. The practice has remained largely detached from the typical applications handled by individual operating companies. The CCIF recommendations have the earmarks of restrictive legislation carefully limited to applications of international scope where such procedure can be justified. Though both cases thus have failed to include the regional and general short-haul users of carrier systems, the development of a nation-wide toll dialing system and the network coverage required by the SAGE comprehensive defense communications have shown that long-haul and short-haul toll circuits have many points of interconnection. In the growth of a telephone company's share of the network, circuits may gradually mature from short-haul to medium- and long-haul extensions. Carrier systems of the greatest concentration of voice channels may often develop at the short-haul toll end links.

Short-haul carrier systems are no longer of the low-channel capacity type, a characteristic which had led to the working assumption that such systems are less critical and require less care in planning and operation. There is less and less justification for planning carrier systems as individual answers to a sectionalized transmission problem. Clearly, the time has come to work uniformly with carrier frequencies at the network junction points.

Blueprint for Carrier Networks

Communication networks in the United States and Canada, as in some other countries, are operated by a fairly large number of separate companies, many of which are growing in physical size at a phenomenal rate. Under such pressure, the familiar paradox exists where uniformity and standardization between many groups is least practical when it is most needed.

Considering the present growth of telephone companies, it seems natural for a carrier system manufacturer to attempt to satisfy the needs of all these users by thinking in terms of their network requirements and by searching for a common solution acceptable to all. Thus, a master plan was developed (since introduced as the "*45* Concept") based upon the following considerations.

NETWORK FACILITIES

The telephone industry's four types of toll facilities must all be usable in the carrier network. These are open-wire lines, paired cables, coaxial cables, and radio links.

CARRIER-SYSTEM FREQUENCY-ALLOCATION SCHEMES

The investment in predominant and time-approved frequency allocations must be guarded and continued to best advantage. Thus, in North America there are now two standard open-wire line carrier allocations, one of which is also traditionally preferred in other parts of the world. There would seem to be no point to the creation of a new non-co-ordinating scheme although a fresh approach might conceivably be more convenient from a network standpoint.

CHANNEL GROUPS

The outstanding characteristic of the carrier network versus the traditional voice network is the provision of channel groups rather than individual voice channels. The entire network concept must be designed around blocks of frequencies which contain transmission of several channels. The $J/K/L$ and CCIF systems have settled on a 12-channel group located at 60–108 kc, and a 60-channel group at 312–552 kc. As in any standardization, however, there is nothing inevitable about such frequencies. With the field wide open at the short- and medium-haul operating level, it was felt that groups could be established which would permit the least cumbersome modulation techniques for line transmission in the most widely used carrier system allocations. In addition, a group with less than 12 channels seemed necessary, as evidenced by a large-scale use of 3- and 4-channel carrier systems.

The groups finally evolved were the following:

1. A 4-channel block of 8–24 kc, termed a "pregroup."
2. A 12-channel block of 40–88 kc, called a "basegroup" in conformance with CCIF terminology.
3. A 24-channel block at 40–140 kc, termed a "double basegroup."

Larger groups may be adopted as the need arises, with the established 60-channel "supergroup" of 312–552 kc the next logical increment.

EQUIPMENT BLOCK-BUILDING DESIGN

To get all the benefits of carrier network operation, the equipment must be arranged in separate blocks as follows:

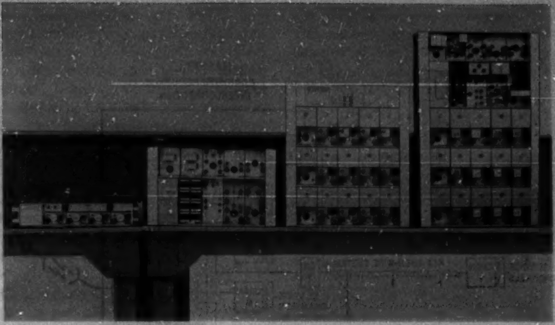

Fig. 7. Four of the building blocks of a 45-class carrier network. From left to right: Four-unit compandor shelf, 24-channel group terminal for multipair cable, 12-channel bank with 12 channel units and four pregroup units, and a 12-channel terminal assembly which is effectively a combination of a 12-channel group terminal and a 12-channel bank. The height of the 12-channel terminal is 31 1/2 inches

1. Equipment for a particular transmission facility with the effects of transmission corrected by the processes of amplification, regulation, equalization, and including modulation to provide group frequencies of one of the standard groups. This equipment is called a "group terminal."

2. Channel banks for the local termination of groups of voice channels, connecting in this case to the associated group terminals.

3. Optional equipment blocks as required for connecting group terminals together, and for voice channel drop requirements. In this class also are group increments of channel compandors, a device required only on certain transmission facilities for toll quality from a noise standpoint. Further included is equipment to connect the American Telephone and Telegraph and CCIF type of 60–108 kc transmission equipment where required. Typical major equipment blocks are illustrated in Fig. 7.

EQUIPMENT STANDARDIZATION

Less than optimum network economy would be realized if each of the equipment blocks used was unique and peculiar. It has been possible to subdivide the major building blocks into types of units which can be repetitively used. From a maintenance and circuit reassignment standpoint, the possibilities of the carrier network concept are perhaps equal to or greater than the immediate benefits at planning and installation time.

In a telephone toll office where open-wire line, cable carrier, and perhaps some radio systems terminate, it has been hitherto typical to service each carrier terminal equipment with completely different spare parts and instructions. However, the new channel banks employ the same units on the terminals for any facility.

This standardization also has the benefit of providing voice channels of uniform toll quality regardless of the transmission medium. Differences in short-haul versus long-haul treatment are confined to the group terminal equipment tailored to the particular facility's operating scheme.

Applications

Characteristic applications for carrier networks occur on toll telephone trunks between cities partly connected by open-wire and partly by conventional voice-frequency balanced cable. Such an application was described in an earlier paper.[5]

One particularly fertile field of application is the rapidly growing use of radio for toll routes. As radio systems operating at microwave frequencies tend to permit simultaneous transmission for several hundred voice channels, it is natural to utilize branching and local dropping of carrier frequency channel groups on such systems. Moreover, many radio installations are located away from the city for space propagation reasons, with long wire-line or cable connections to the toll office. With carrier network interconnection equipment, the city-to-radio-station transmission can be handled on a co-ordinating, standard basis with no channel terminal equipment required at the radio site.

An actual example of a typical complex network application is illustrated in Fig. 8. This application involves the establishment of a new radio toll route and of new

open-wire carrier systems in the territory of the General Telephone Company of the Southwest. At present, the exact layout is tentative and still subject to change.

The telephone company has the problem of retiring a presently existing manual toll center as a part of a dial conversion program. Voice channel concentration between the new combined toll center at Seymour, Tex., and the distribution point at Haskell, Tex., is large enough to favor the economy of a microwave radio system.

From Haskell, which will become an unattended office, channel groups from the radio terminal will be directed to their respective assignments on a number of radiating open-wire leads. The characteristics of these leads are such that they will involve the use of *45A* carrier systems (*J*-co-ordinating), *45C* carrier systems (*O*-co-ordinating), and voice-frequency circuits. A total of seven different locations, including Haskell, will be connected with the Seymour office. Four of them will be served directly by the *45*-class carrier network with carrier-frequency interconnections at Haskell. The remaining three towns will continue to be served by voice-frequency interconnection at Haskell as there are suitable existing facilities.

Many networks such as the one shown in Fig. 8 are now in the planning and installation stage, and will unquestionably increase in numbers as more of the various equipment building blocks become available. There will be great need for many 4- to 24-channel direct, high-usage groups in the continental toll-dialing network.

Considering all possible applications of the carrier network concept, however, it is apparent that some logical limit will be encountered for the number of times the same channel group can be expected to enter and withdraw from connecting points. As a generalization, the frequency of interconnection of one and the same group would increase inversely with system length. Short-haul trunk groups may be expected to run through as many as six tandem carrier connections. With respect to over-all group-transmission quality, the group transmitted through many interconnections will perform about equally as well as a single long-haul system with many repeaters.

There are and will continue to be applications for hitherto conventional-type carrier systems, where the voice-channel requirement is very low or where interconnection with other channel groups is not usually intended unless in steps of one channel at a time. Another application of conventional-type carrier is in the exchange and subscriber telephone plant where the use of carrier is still in its infancy. At the present time it is in toll or similar nontelephone long-distance traffic that network carrier will find most use.

In the step-by-step development of a program such as outlined here, judgment must be constantly exercised to arbitrate between the pure concept and the pressure for prompt field application. Idealistically, it might be proper to develop the complete line of carrier network equipment with all offshoots for standard applications in one gigantic effort, if the industry would stand still long enough to settle on the range of applications known at the outset of such a program. Such an approach is not realistic, however, and might very well impede further advances of the art. By contrast, the concept of carrier networks may be considered timeless within reason if flexibility and compromise are used in its implementation.

A step-by-step approach has permitted piecemeal releases of systems and equipment building blocks, creating a skeleton of potential networks. Some equipment items have appeared which are combinations of building blocks, serving the same concept by elimination of plug-in units rather than by original reduction in effort to the smallest possible block increment.[6] In this third year of established field use, equipment for some of the open-wire applications is still not available, as preference had to be given to group terminal equipment for radio and cable.

From a technological standpoint, the experience of the past year has already shown that such a concept is fully compatible with the idea of progress in the communications art. For example, when the all-carrier network equipment was conceived, transistors were known only as interesting specimens for experimentation; hence, the first equipment made available was designed around vacuum tubes. Now, as additional equipment items are under development, transistors are used in preference to vacuum tubes. Future techniques of mass production and equipment simplification need not conflict with the standard group frequencies and interconnection techniques. These standards are of such a classic simplicity that their usefulness is assured for a long time to come.

Conclusions

The universal transmission of speech- and voice-channel-type pulses requires networks in which carrier frequencies rather than voice frequencies must be considered. A master plan for carrier-frequency operation in all types of communication networks provides the desired standards of connection coupled with greatest practical economy in equipment. This network concept makes carrier at home on all practical facilities and leaves the operating company free to plan to traffic requirements instead of to equipment limitations.

Lightning Protection on the Stevens Point—Wisconsin Rapids Intercity Telephone Cable

R. C. DOWLING
ASSOCIATE MEMBER AIEE

Synopsis: It has been a common assumption that buried telephone cables are practically free from the destructive effects of lightning, particularly intercity cables which have no intermediate terminals or connections to local subscriber installations along the route of the buried section. Such cables in some areas, however, have been found to be relatively vulnerable to damage from lightning strokes occurring along the route of cables. To avoid such damage various methods have been employed. One method has been to plow shield wires in the ground above the location of the cables. Whether or not such protection is provided is customarily based on balancing the cost of such measures against the expectancy of lightning strokes per year along the respective route, and the anticipated cost of repairs and interruptions entailed. This paper describes a situation where the anticipated troubles did not appear to warrant the cost of the initial installation of shield wires, but later experience indicated the need for some remedial measures. The measure adopted consisted of the installations of full-count carbon gap protection at various intervals along the cable route.

DURING 1946 an intercity telephone cable was placed between Stevens Point and Wisconsin Rapids. These small cities are centrally located in the State of Wisconsin. The cable followed the route of the Stevens Point–Minneapolis coaxial cable from Stevens Point for a distance of approximately 10 miles. Of this distance, approximately one mile is in conduit in the city of Stevens Point, and the remainder is aerial on the same poles with the coaxial cable. Beyond this aerial portion, approximately 9 miles are buried about 30 inches in the ground. Another length of approximately 1/2 mile is in conduit in the city of Wisconsin Rapids. Approximately 2 miles south from the junction of the aerial and buried cable, a terminal serves one phantom group of open wire, extending approximately 1/2 mile to the village of Rudolph. This terminal was equipped with a protector providing 700-volt gaps to sheath on the pairs in use. Fig. 1 shows the route of this cable and other pertinent data.

Cable Specifications

The cable is made of 19 quads of 19-gauge copper conductors, which are paper insulated and enclosed in a lead sheath. A double paper wrap between the conductors and sheath provides a dielectric strength of approximately 4,000 volts. The part of the cable plowed directly into the earth has a double serving of jute impregnated with a preservative compound over the lead sheath. The aerial part and that part in conduit have no protection over the lead. The logitudinal resistance of the lead sheath is 2.38 ohms per mile.

Preliminary Studies

In intercity cables, lightning damage normally occurs because the lightning current raises the potential of the sheath sufficiently above that of the conductors to cause insulation breakdown to some

Fig. 2. Buried toll cable between pole 389 and Wisconsin Rapids

of the conductors near the sheath. These conductors are then raised in potential and may break down to other conductors at scattered locations wherever the insulation is the weakest. The usual mitigative procedure is to limit the sheath potential rise by shield wires or to increase the insulation between the sheath and conductors. These measures can best be applied in the design of new cable installations.

Before the installation of the cable, a study of the probable lightning hazards was made. Earth resistivity tests indicated the average resistivity to a depth of 40 feet to be 400-meter-ohms at point no. 1, 118-meter-ohms at point no. 2, and 54-meter-ohms at point no. 3. The locations of these test points are shown in Fig. 2. Note that each test point is approximately in the center of a 3-mile section.

With the use of the lightning storm incidence for the area, the longitudinal sheath resistance, and the above-earth resistivities in curves available at the time, it was estimated that the following should be anticipated: 1.2 cases of lightning damage per 100 miles of sheath per year in the 400-meter-ohm section, 0.5 cases per 100 miles per year in the 118-meter-ohm section, and negligible damage in the 54-meter-ohm section. This can also be expressed as one case of damage every 28 years in the first section and one case every 67 years in the second section. At that time, it was estimated that shield wires would reduce the expected damage rate to 0.77 cases per 100 miles per year in the first section and 0.32 cases per 100 miles per year in the second section. On the basis of these computations, the cost of shield wires could not be justified.

Although this paper is not primarily concerned with the aerial portion of the cable, it is of interest to note that the aerial portion of this cable and the coaxial cable are protected by pole protection wires and a buried shield wire.

Initial Experience

The buried portion of the cable was plowed into the ground during the spring. Before it was spliced, lightning damage occurred in three different pieces. Accurate information as to the extent and location of this damage was not recorded.

During 1947 scattered minor burns in the buried portion of this cable occurred at 14 locations. These points are indicated

Vol.
Pt. 1
1956

Fig. 3. First protected terminal north of Wisconsin Rapids looking north

on Fig. 2. Although some of this damage was definitely new, it was thought that part of it might have been caused by not clearing completely the previous trouble. Accordingly, there was no great concern over this damage and no mitigative measures were considered at that time. No major lightning damage to the buried portion of this cable was reported during 1948, 1949, or 1950.

1951 Damage

During a storm on July 16, 1951, the cable was damaged severely. Trouble occurred at 39 scattered locations. An analysis of the damage indicated the cause was three or four separate strokes of lightning. Fig. 2 shows the general location of this damage.

The most severe stroke occurred on a small tree located approximately 5 feet from the cable. This tree was shattered so completely that only a stump about 4 feet high remained. A large hole was blown in the ground to the depth of the cable. The cable was burned completely in two with the ends left sticking up clear of the earth. There was no visible evidence above ground of lightning strokes at any other locations.

The tree involved was 3 to 4 inches in diameter and showed signs of having been injured when small. It apparently had been just a crippled sapling when the cable was placed and was not considered worth cutting down. It must have grown rapidly, however, because the debris found indicated that it had been 10 to 15 feet tall. There were no other trees near.

A survey of these damages shows a group of four burns located within a mile north of the point where the 118-meter-ohm resistivity test was made. Two of the burns experienced in 1947 also had been in this locality.

Another group of five burns occurred very close together about 1/2 mile south of the location of the 118-meter-ohm resistivity test. This group, however, involved only open and crossed pairs, and the cable sheath was not involved in any of the burns.

Burns were scattered a distance of over a mile in the vicinity of the stroke to the tree described in the foregoing. Some of these were single burns and others were in groups. Many of the burns involved only conductors, but others involved the sheath and could have been caused by separate strokes.

A final group of burns occurred a little less than 1/2 mile south of the location of the 400-meter-ohm earth resistivity test. Although only five burns were listed at this location, several other troubles, which were not located exactly, were cleared by replacing a 25-foot section of cable.

Further Damage Expectancy Studies

In view of this severe damage, the need for special protective measures again was examined. The earth resistivity tests were repeated and values of 460 meter-ohms, 185 meter-ohms, and 70 meter-ohms, respectively, were obtained. These values are considerably higher than the previous tests in the same general locations. Using newer curves, the lightning damage expectancy was again calculated and found to be 3 cases per 100 miles per year in the first 3-mile section, 1.2 cases per 100 miles per year in the second section, and in the third section negligible. With two *104* copper shield wires, it was calculated that the damage expectancy would be reduced to 0.8 cases per 100 miles per year in the first section and to negligible trouble in the second section. This would be a reduction of 0.066 cases per year in the high-resistivity 3-mile section and a reduction of 0.036 cases per year in the medium-resistivity 3-mile section.

These estimates are based on locating the shield wires approximately one foot apart and one foot above the cable. To place the wires it would be necessary to locate and stake accurately the cable for route and depth. A 2-share plow would then have to be assembled specially for the job.

It was thought that the trouble expectancy figures discussed in the foregoing might be low. In an attempt to verify this, a study was made of the records for the Neillsville–Eau Claire section of the Stevens Point–Minneapolis coaxial cable, which is buried under somewhat similar circumstances. This cable is protected by two *165* copper shield wires. The records showed a damage incidence of 3.1 cases per 100 miles per year. This is 2.6 times as much damage as was estimated using the same method previously mentioned. Assuming that the expectancy figures for the cable under consideration were increased in the same proportion, there would still be an improvement of only 0.17 cases per year for the high-resistivity 3-mile section. It was still felt that this was not sufficient improvement to justify the cost of the shield wires. It was decided to study the matter further and to await results of studies being made by the Bell Telephone Laboratories in the east.

Fig. 4. Second protected terminal north of Wisconsin Rapids looking south

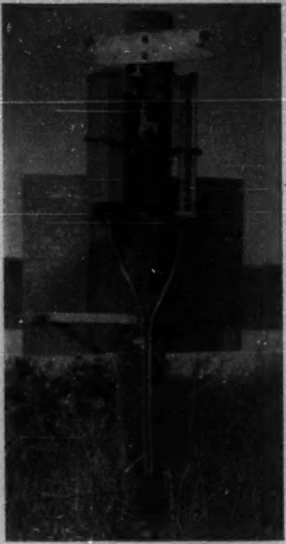

Fig. 5. Third protected terminal north of Wisconsin Rapids looking south

1953 Damage and Remedial Measures

During a storm on July 1, 1953, the cable was again damaged. In this case trouble occurred at four scattered locations in the north mile of the high-resistivity section. Although there was no above-ground evidence of lightning strokes at two of the locations, sheath to conductor burns occurred, indicating a near-by stroke. At the other two locations only conductor to conductor burns were involved.

It was decided that some action now would have to be taken. Two years before, full-count protection, which consists of carbon gaps between every conductor in a cable and the sheath, had been placed on an aerial intercity cable where it crossed a high rocky ridge and had been persistently damaged. In this case, there was a terminal serving a radio station near the middle of the exposed section. Because some conductors were brought out and protected, it was considered desirable to add protection for all other conductors in the cable at this location. Full-count protection provides a path through the carbon gap between any conductor and sheath, and through two gaps in series between any conductor and any other conductor in the cable. Potentials should thus be equalized in the cable without insulation breakdown. This method is normally used on local cables where conductors are frequently brought out and connected to exposed wire or to subscribers' stations. In dealing with intercity cables, it is usually considered more practical to isolate completely the conductors from the sheath, by means of higher breakdown insulation.

The full-count protection had been remarkably successful in eliminating the persistent damage in the case previously mentioned and it was decided to apply it on the Stevens Point–Wisconsin Rapids cable. A 26-pair and a 16-pair protected terminal were placed on a marker post at two locations. One was placed in about the center of the 3-mile section of highest earth resistivity and the other approximately $1^1/_2$ miles to the north. These locations are shown on Fig. 2 with the installations shown in Figs. 3 and 4. These terminals were bridged onto the quads in the cable and provided a 700-volt carbon gap to the sheath on all pairs. This work was completed during the fall of 1953, but before that time two more burns had been found in the high-resistivity earth area. In neither of these had there been a breakdown to the sheath. It is believed that this trouble may have been caused by old burns, possibly from the July storm of that year.

1954 Damage and Extension of Remedial Measures

On July 3, 1954, the buried cable was damaged at eight scattered locations. This damage in general, was centered around the junction with the spur to Rudolph. There was one burn, however, quite near the junction with the aerial cable. The spur to Rudolph consists of a little less than 1/2 mile of open wire, terminating in repeating coils on the terminal pole. Two of the pairs connected at this terminal were involved in a burn to sheath in a sleeve on the terminal pole and in some of the burns in the main cable. Protection at the Rudolph office was not operated and the repeating coils on the pole were not damaged. It appears that the lightning was not brought into the cable from the aerial wire, but by a rise in sheath potential caused by lightning strokes to ground. This damage is located in the area of lowest earth resistivity where estimates of trouble expectancy indicated negligible damage.

In view of this damage in the low-resistivity earth area, it was decided also to place protected terminals on the cable in this area. Terminals as described in the foregoing accordingly were added at a point near the junction with the aerial cable, at the location of the spur to Rudolph, and at a point about midway between this location and that of the northmost terminals placed previously. These locations are shown on Fig. 2 and the installations are shown in Figs. 5 and 6.

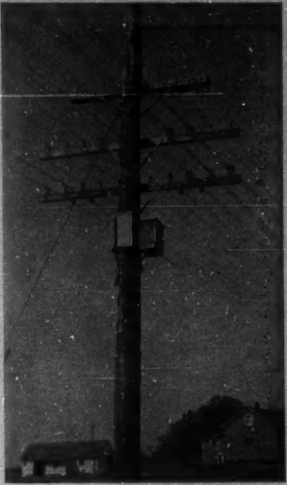

Fig. 6. Terminal pole at spur to Rudolph

At this time a microwave tower was being planned in the area east of Rudolph and the supervisory circuits were to be routed from the same terminal. The full-count protection at this location was provided with the rearrangements necessary to make these circuits available.

With the investigation of this latest damage, two isolated trees were noted which were quite near the cable route. Although these trees showed no visible evidence of having been struck by lightning, it was thought that they constituted a potential hazard and arrangements were made to have them removed.

The installation of the protected terminals and the removal of the trees was completed late in 1954. During 1955 and the early part of the 1956 lightning season, no lightning trouble has been experienced on this cable.

There was considerable concern about the possibility of excessive service interruptions caused by permanent grounding of the carbon gaps in these terminals. The maintenance personnel were instructed to report any such occurrences.

For the period of over 2 years for the first two installations, and over one year for the latter three installations, service interruptions have occurred on only one occasion. On other occasions, after heavy storms, the blocks were examined and found to be heavily dusted.

Conclusions

It is recognized, that this short period is not adequate to indicate fully the value of this method of protection for intercity cables, since longer periods have occurred without damage. It will not be possible completely to evaluate the method in this case, because a new cable along the same route is being planned for installation late in 1956 or early in 1957. This will have a shielding effect on the existing cable. The new cable will have what is called Lepeth sheath. This consists of a layer of extruded polyethylene between the conductors and the lead sheath. Insulation between the sheath and conductors with a dielectric strength of over 20 kv is provided. This type of cable, when carefully spliced to maintain the full dielectric strength through the splices, is very resistant to lightning damage.

The lapsed time is not sufficient to establish definitely the effectiveness of this method of protecting intercity telephone cables, but its consideration for adoption in similar situations appears warranted.

Electronics in Telephone Switching Systems

A. E. JOEL
MEMBER AIEE

DURING the last 40 years a great background and fund of knowledge has developed in the field of telephone switching. Constant improvement in available devices has resulted in an increased scope of application. The field has almost reached a point of perfection as an art and is now rapidly entering a more scientific era.

The tools of the present-day telephone system design engineer are well known; shown in Figs. 1(A) and 1(B) are the relay and the various forms of electromechanical switching apparatus. But over the years, while the art employing these tools was developing, the field of electronics has been developing also. Electronic applications have formerly been most important in relation to sensitivity rather than speed. Even in the telephone switching field, this property of sensitivity has provided better signaling and more accurate timing.

With World War II, however, came a recognition of the speed advantages of electronics. This characteristic was exploited primarily in the quantizing of information in both transmission and information-processing equipment. In the latter field, new digital computers made their appearance and resulted in the development of new forms of electronic devices, most important of which are the "bulk memory" devices.[1]

In the postwar period, the exploitation of another phase of electronics developed from research in semiconductor devices. The transistor is perhaps the best-known invention to emerge from these investigations. The impact of the application of semiconductor devices is yet to be felt in the electronics industry and it will most likely find greatest application in the information-processing field and in communications generally.

Before one can understand and appreciate the impact that electronics will have on the design of new telephone switching systems, it is necessary to consider the question: "What is a telephone switching system?" By evolution it is now generally recognized that the central office portion of a telephone switching system consists of two principal parts, the interconnecting network, or conversation channel, and its control, and certain physical and operational characteristics of these parts; see Fig. 1.

In some switching systems, particularly the progressive direct-control type such as the step-by-step system, these parts are inexorably integrated. In the modern systems, however, they have largely been separated. For purposes of the following discussion, the common-control type of system will be assumed. The bulk nature of the electronic memory devices makes them more readily adaptable to systems of the common control type, where the control functions consisting of the receipt, interpretation, and processing of input signals, and the effecting of output signals, may be concentrated.

Interconnecting Network

In electromechanical switching systems the interconnecting network is composed of crossbar switches or other electromechanical devices. Each connection through the network is physically separated in space from the others and hence this network can be called generically a space-division type. It is subdivided functionally into the concentration stage, where active lines are separated from those not being called or served at a particular time; the distribution stage, where interconnection of active lines and trunks is accomplished; and an expansion stage, where active call paths are connected to selected destinations.

In electronic switching systems, three classes of switching networks have been described[2]:

1. "Space division," similar to the space division for electromechanical apparatus except that electronic devices such as gas tubes are employed in place of mechanical contacts as the crosspoint element.[3]
2. "Time division," where calls are samples in time, each one being given a time slot on a single channel.[4,5]
3. "Frequency division," such as employed in carrier systems where each call is modulated to a different frequency level on a single transmission medium.[6,7]

In electronic switching the interconnecting networks derive their basic characteristics from the known methods of telephone transmission. Since transmission techniques are used it is generally not feasible to pass d-c signals through such networks. Also, certain a-c signals such as 20-cycle current which are now

used for ringing are of a power level so high that they would overload the electronic switching devices employed. It thus seems that to accomplish switching with an electronic interconnecting network, a change is required in the customer's apparatus to make it capable of responding to a lower level alternating current for the call signal. Telephone sets with transistor amplifiers and an acoustical horn are being developed. Interrupted tones in the voice-frequency range can be used effectively to call the user to the telephone.[8]

As in most electromechanical switching networks, the concepts of connecting successive stages of switching devices (stages to perform the functions of concentration, distribution, and expansion) to form the network also apply. Since there is more than one method of interconnection, the successive stages of a network may employ either electronic or electromechanical switching techniques, or both. In electromechanical switching, different devices may also be used in different stages.

In electromechanical space-division networks, certain types of crosspoints are better adapted to common-control operation than are others. Systems with electromechanical selector switches most generally are set progressively. In systems with relays or relay-like crosspoints, all crosspoints involved in a connection may be actuated simultaneously. In either case the switching device, or the circuit in which it is used, has a form of memory. This memory, shown as M in Fig. 2, may be the ability of a selector to be held mechanically in a particular path-connecting position or in a locking or holding circuit associated with a crosspoint relay or crossbar switch magnet.

To minimize the time consumed by the common-control elements, simultaneous operation of relay or relay-like crosspoints is most desirable. However, this type of network requires a grid of link testing and control leads such as shown in Fig. 3 for a typical stage of a crossbar switching network. In a network of this type, the calling rate capacity is limited by the slow actuating speed of the electromechanical relay or switch. Efficient network configurations can be devised for large capacity. To set up connections at a high rate in such a network requires a plurality of controls, each capable of operating on all or part of the network. In any case, the controls function in parallel on the network because of the speed considerations.

With electronics applied to space-division switching networks, two improvements over the operation of relay-type space-division networks may be achieved. First, the speed of operation of the crosspoint elements may be made high enough so that only one control is needed to operate on networks of the size now requiring a plurality of controls. Second, the properties of proposed electronic crosspoint elements are such that the principle of "end-marking" may be employed; see Fig. 4.

Here in contrast to the grid of testing and actuating wires required in electromechanical versions of space-division

networks, the electronic space-division switching network requires only the selectors at each end of a desired network connection to apply the marking potentials. The electronic crosspoint element will be actuated if the link to which it connects is idle. Eventually all available paths between input and output will be marked. As means must be provided for sustaining only one of the possible idle paths, the memory property of the crosspoint device takes over to hold the path until it is released by release marks or removal of the sustaining voltages. In space-division networks, the memory requirements must be satisfied just as in electromechanical networks.

Multiplexing and carrier transmission systems[9] employ time and frequency division but the physical terminals at both ends of a channel for which the facilities are derived have a 1-to-1 correspondence which can only be changed manually. In a switching system, the input-output relations must change automatically as required for each call. Here the need arises for a changeable memory for associating a given time or frequency slot to a particular call at any given time. At some other time, these points in time or frequency must be capable of being assigned automatically to different inputs and outputs. For the period that they are assigned, some form of memory must record this assignment and this memory is consulted continuously or periodically for the duration of the call.

With time-division switching, this new concept in the use of memory in a switching network appears most clearly; see Fig. 5. To associate an input with an output during a time slot, the memory must be consulted which associates the particular input with the particular output. To effect the connection during a time slot the input and output must be selected. A memory is consulted to operate high-speed selectors simultaneously for both the input and output. Each selector receives information from a memory which actuates crosspoints to associate the input or output with the common transmission medium. The information from the memory which controls the selection process is known as an "address." The crosspoint is nonlocking since it must open when the selector re-

ceives its next address. The individual memory of crosspoints for space-division networks has thus been changed by time division to changeable memory, usually in the form of a coded address associated with each time slot. Furthermore, since the successive addresses actuate the same selectors and hence may be held in a common high-speed device, electronic bulk memory is ideally suited for this task. The memory must be changeable to allow for different associations of input to output at different times.

In frequency division, the control characteristics of the interconnecting network require a modulation frequency to be assigned to each simultaneous conversation applied within the bandwidth of the common medium. As shown in Fig. 6, the application of the modulation frequencies requires a separate selector for each input and output. These selectors are nothing more than space-division switching networks and therefore require memory in the switching devices whether they are electromechanical or electronic.

In addition to memory for associations within the switching network, selecting means are also needed to activate a terminal to be chosen in space division (e.g., Fig. 4), to place address information in the proper time slot in time-division switching, or to set the frequency-apply-switching network in frequency division.

Control

The control of the switching system provides the facilities for receiving, interpreting, and acting on the information placed into it. In particular this is the address of the output desired. A service request detector (SR-D) is provided for each line or trunk.

In electromechanical systems these logic- and information-gathering functions are performed by relays or electromechanical switches. In order to keep up with the flow of information from a large number of customers, a number of register circuits must be provided to perform the same function simultaneously on different calls. Here information is being gathered on a space-division basis and a control switching network may be visualized as shown in Fig. 7. Registers *R-M* constitute the memory used to store the input information as it is being received in a sequential manner from lines and trunks. As in the case of the conversation-switching network, a space-division control-switching network has been used in electromechanical systems because the speed of these devices is not adequate to accommodate the rate at which information flows into the system. In the step-by-step system the control and conversation switching networks are coincident. In the no. 5 crossbar system[10] the same network is used for both control and conversation on call originations but the functions are not coincident, that is, the network is used for either control or conversation. In other common-control systems, separate control networks known as "register or sender links" are employed.

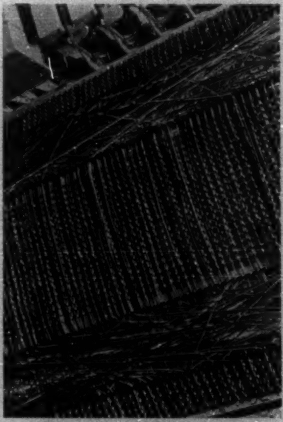

Fig. 12. No. 5 number group

When relays are used to receive the information pulsed into the office by customers or operators, a plurality of register circuits is needed. The number of registers required is determined by the time necessary to actuate the calling device and for it to pulse in the information. The registering function has one part to detect or receive the information and a second part to store it until a sufficient amount has been received for processing. The processing function is usually allotted to other circuits such as the markers in crossbar systems.

Since the input of information to a switching system is usually limited to two conductors, a serial form of signaling is used. It would seem only natural that if a detector were fast enough, it could function to receive the serial information on several simultaneously active inputs. Relays are not fast enough to accomplish this, but high-speed time-sharing electronic devices have been designed to perform this information-gathering function. Since it is a time-sharing arrangement it is analogous to the time-division switching. A time-division control access as shown in Fig. 8 requires memory to control the time-division switching functions. Time sharing as applied to the gathering of information in telephone switching systems has been called "scanning." The individual register memories are still in parallel form because of the relatively long time required for sufficient information to be received before processing may start. Higher speed means for placing information into switching systems, such as pre-

Fig. 13. AMA translator

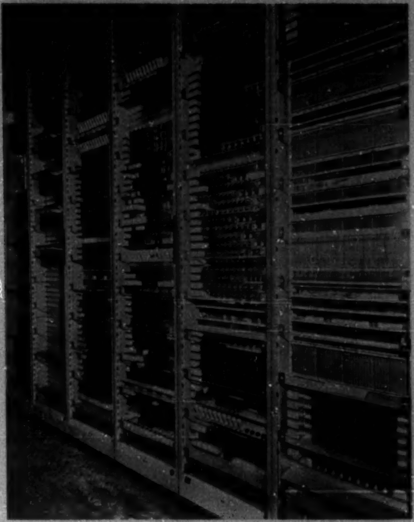

Fig. 14. No. 5 route relay frame

set keysets, is one way of reducing, if not eliminating, this need for parallel register storage in the switching system prior to processing. However, with this type of device one merely transfers the location of the storage from the central office to the customer's telephone set. The fundamental limitation is the rate at which a human being is able to transfer information from his brain into some physical representation. A time-division control access with separate functional memory is shown in Fig. 9.

Fig. 15. No. 4A card translator

Lower cost memory is a practical means for improving this portion of the switching system.[9] Many small low-cost relay registers have been designed and placed in service.[10] Electronics, however, offers memory at one tenth, or less, of the cost per bit if used in large quantities with a common-memory-access control. New low-cost bulk electronic memories are now available to be used in this manner. As shown in Fig. 10, the memory for the control of the time-division control access network and the register memory may be combined in the bulk memory.

Memory appears in the control portion of a switching system in many ways, some obvious and others more subtle. Fig. 11 shows a typical electromechanical switching system, much like no. 5 crossbar. The active memory, designated A, includes call information storage A_2 whether in a register, sender, or marker during processing. There is also certain pertinent call information storage associated with trunk circuits such as a no-charge class on outgoing calls or the ringing code used in incoming calls. Another type of active memory A_1 has been mentioned in connection with switching networks to remember the input-output associations. In most electromechanical systems active memroy has been implemented with relays or switches.

Another form of memory is also employed in all telephone switching systems and much effort has been devoted to devising improved means for effecting a memory that is not changed with each call but is of a more permanent nature. Examples of this passive memory, P in Fig. 11, are the translations required in common-control systems to obtain certain flexibility between the assignment of lines to the switching network and their directory listing. These translations between equipment numbers (network location) and directory numbers are required to direct incoming calls to the proper ter-

minals, such as the number group frame in no. *5* crossbar of Fig. 12, and to provide information for charging purposes on originating calls, such as the AMA "dimond" ring translator[11] of Fig. 13. Each of these translators for a 10,000-line office represents about 10^6 bits of information. Passive memory is also used to translate central office codes into routing information. In local central offices this is also done by cross-connections as shown in Fig. 14.

Another form of passive memory is the punched card or tape used in telephone accounting systems. A step toward electronic memory is the card translator which provides routing information in the crossbar toll switching system,[12] see Fig. 15. Here the cards represent passive memory and are selected and read by a combination of electromechanical action and light-beam sensing with phototransistor detectors. One such device equipped with 1,000 cards represents the storage of approximately 10^6 bits of information.

In all of these types of passive memory, speed limitations are involved in the choice of devices used within the memory or the access to it. This is one reason why these translators are subdivided so that the various portions may be used in parallel in order to satisfy the total information-processing needs of the office.

A discussion of passive memory would not be complete without one further illustration. Fig. 16 is a wiring side view of a typical relay circuit in the information-processing portion of a switching system. It could be any other unit, such as a trunk circuit, but in any case each wire on such a unit is remembering some passive relationship between the active portions of the circuit, such as relays. This is the memory of the contact and coil interrelationships as conceived by the designer and based on the requirements of what the circuit is required to accomplish. It is the program of what the central office must do at each step of every type of call. Modern digital computers have been built with the ability to store programs in bulk memories for the solutions of the various types of problems put to them. It is conceivable that the program of a telephone central office may also be stored in bulk memories to eliminate the need for much of the fixed wiring such as appears in relay call-processing circuits.

The form of memory available in electronics is considerably different from that which has been previously available.

Electronic memory has been characterized as "common-medium" or "bulk" memory. Here, a single device is capable of storing more than a single bit of information, which is the limit of most relays or other devices capable of operating in a bistable manner. A number of different types of electronic bulk memories have been devised for digital processing. They differ appreciably in physical form, each taking advantage of the phenomenon of some different area of the physical sciences—electrostatic, electromagnetic, or optic. Magnetic tapes[13] and drums[14] (Fig. 17), cores[15] (Fig. 18), electrostatic storage in tubes[16,17] (Fig. 19) and ferroelectrics[18,19] (Fig. 20), and photographic storage[20] (Fig. 21) are available.

Several properties of these memory devices are of interest, the primary being the speed with which stored information may be read. This is known as "access speed." Another property of these common-medium memory systems or devices is the ability to change what has been written. If the changes can be made rapidly enough, they may be used in electronic systems in much the same manner as relays are used in electromechanical systems to process information. If the change must be made relatively infrequently, such as changing photographic plates, they may be used as substitutes for the type of memory in these systems which are provided by cross-connections and wiring. The required fixed or semipermanent electronic memory may be characterized primarily by a high reading speed, large capacity, and the ability to hold stored information even during prolonged intervals of loss of power. The amount of memory is measured in terms of binary digits or "bits." The number of bits equivalent to a single cross-connection can be rather large. Therefore, an electronic memory replacing a fixed memory such as in the card translator in modern electromechanical systems should be high in bit capacity, say from 10^6 to 10^7 bits for 10,000 lines.

One way in which electronic memory for various system applications may be evaluated is given in Fig. 22. This chart shows, for the various forms of storage, the relation between the capacity in bits and cycle time, which includes access, reading, and, if necessary, the regeneration time of the stored information. For the sake of simplicity, ferroelectric and magnetic-core memories have been combined as co-ordinate access arrays. Single-bit electronic memory will be described in more detail later.

In the control portion of a switching system it is not only necessary to gather

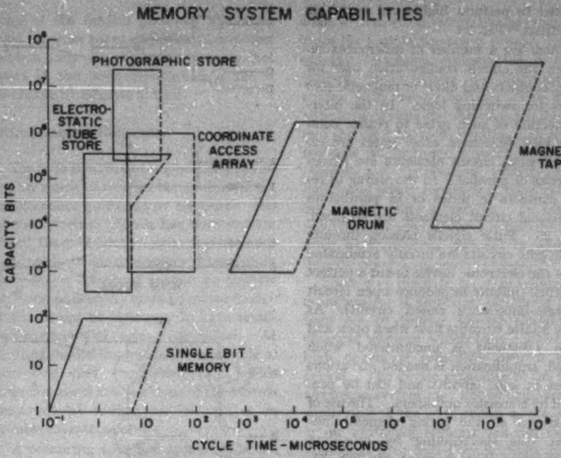

Fig. 22. Memory system capabilities

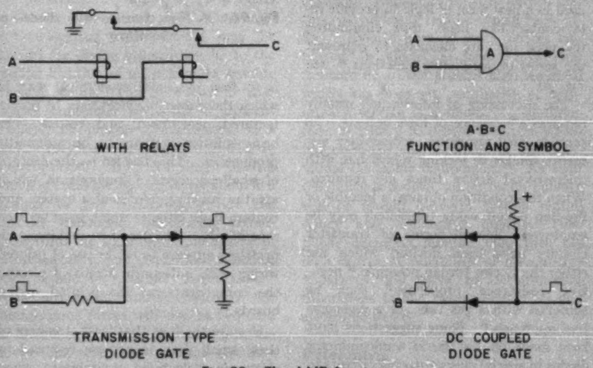

Fig. 23. The AND function

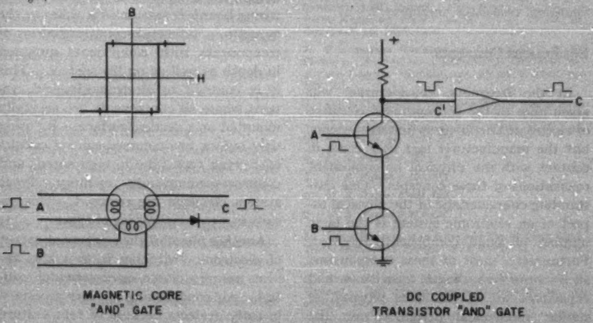

Fig. 24. Other AND circuits

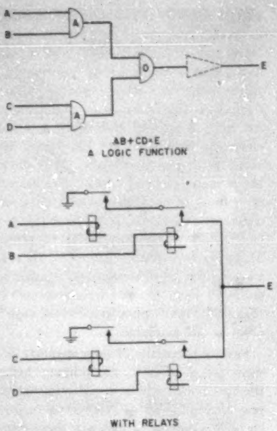

Fig. 25. A logic function with relays

and store information, but the information must be interpreted and appropriate action taken. This function is called "processing." Processing circuits control the information-gathering and storage functions and perform logical functions to produce the necessary flow of information. In the logic circuits of electronic systems, to keep pace with the time-sharing nature of the information-gathering function, the devices used must be several orders of magnitude faster than their counterparts, the relays, of the electromechanical system. The scanning and bulk memory access speeds must be comparable in speed if they are not to create a bottleneck. All portions of the system must be in balance in regard to time.

Devices and techniques for use in the design of high-speed logic circuits are available,[21] and information processing previously carried out by complex relay circuitry may be carried out in microseconds instead of milliseconds. Devices such as semiconductor diodes and transistors seem to be pointing the way to the future in performing these functions.[22] Previously, hot cathode tubes with high power consumption were needed to achieve the same functions at similar high speeds and for a long time this has been one of the greatest deterrents to electronic switching.

Semiconductor diode gate circuits are now quite familiar[23] and take the place of the conventional make-and-break contacts in the electromechanical switching art (see Fig. 23 for the AND function). Magnetic-core circuitry is also being exploited to perform high-speed switching functions,[24] Fig. 24.

There are a number of differences between the circuit configuration used for relay contacts and diode or magnetic-core gates for switching logic. In the interconnection of such gates to realize complex logic functions, other gates are required when circuit elements are placed in series or parallel. In the wiring of relay contacts in series or in parallel no additional circuit elements are required, Fig. 25. Pulse signals passing through diode gate circuits are usually attenuated since the electronic device is not a perfect switcher (infinite-impedance open circuit to zero-impedance closed circuit). As some minite currents flow when open and some resistance is encountered when closed, amplification is needed at various places in logic circuits and can be provided by transistor amplifiers. The use of transistors as the gating element eliminates this shortcoming by providing amplification in each gate; see Fig. 24. Transistors have also been successfully used in a new form of logic to provide relay-contact-like logic, thus eliminating the need for gate elements to represent the series of paralleling functions;[25] see Fig. 26.

The processing of information usually requires a sequence of logic actions. To provide such sequences, momentary elements similar to locking relays but with microsecond action times are required. When this condition obtains, a bistable or flip-flop circuit using transistors may be employed. Several forms of transistor circuits have been devised which use either the Eccles-Jordan principle,[26] negative resistance properties[27] such as achieved with a gas tube, or a regenerative approach.[28] Some suggestions have been made on the use of semiconductor diodes in special energy-storing circuits to amplify pulses instead of the more conventional transistor amplifiers.[29]

Equipment Concepts

In the foregoing, consideration was given only to the concepts and circuitry of electronic telephone switching systems, but the manufacturer and user come in contact with the physical or equipment realizations of these concepts. One outstanding characteristic of the physical aspect of an electronic system is the large number of small components required. Fortunately, most of these components, such as resistors, diodes, transistors, and capacitors, are of the same physical or similar mechanical design. From the manufacturer's point of view, the problem is to find the most economical way in which these many devices may be manufactured, assembled, and tested. The basic solution appears to be automatic production. This has led to the concept of small packages of components, which are the building blocks of a system and contain basic circuits which may be used repetitively. The trend in making such packages appears to be the use of printed wiring with automatic means of placing the components on the printed wiring boards.[30]

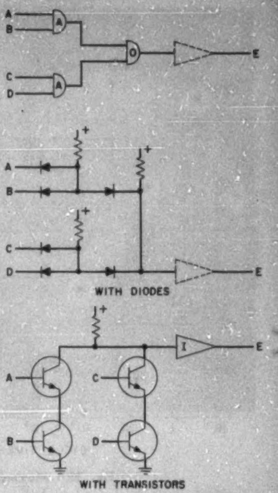

Fig. 26. A logic function with diodes or transistors

Despite the fact that large numbers of these small components are required in electronic telephone switching, when equipment using a multiplicity of printed wiring boards is assembled it takes on the aspect of a 3-dimensional arrangement of components with components mounted in depth as well as on the surface. This is in contrast to electromechanical systems where all components are generally mounted on a vertical surface. By using only one or two common-control circuits of a given type (due to high speed) and common-medium-bulk memory, fewer system elements are required. This results in a material saving of space.

Another phase of the equipment aspect of electronic switching is that the devices require closer environmental control. Air conditioning appears necessary in early systems because of temperature limitations and other characteristics of

Vol.
Pt. 1
195

some of the devices presently available. Also, vacuum tubes and other high-power devices may develop objectionable hot spots in the equipment which make it advisable to exhaust hot air.

Maintenance Concepts

There is insufficient experience at present on which to base an estimation of the maintenance problems of electronic telephone systems. Much has been written about the problems encountered in maintaining electronic computers; however, in designing a telephone system an entirely different philosophy must be pursued since it should not be necessary to have maintenance forces of engineering caliber. At no time should the system be incapable of accepting and completing calls. This does not mean that portions of the system may not be worked on for routine or trouble maintenance.

A promising approach appears to be the use of marginal condition routine tests for detecting in advance components which are about to fail.[31] Automatic trouble-locating arrangements may be devised for giving information as to the specific location of a package in trouble when it occurs. This automatic trouble locator combined with the equipment concept of plug-in units means that service may be maintained without long interruptions. By designing devices which are reliable, by employing them in a manner to give maximum service life, and by judiciously introducing redundancy into the equipment, the chance of simultaneous failure of any two identical parts should be extremely improbable.[32] With automatic trouble locating, the maintenance forces will not be required to have a thorough understanding of the device characteristics and the circuitry used. Centralized repair of defective units as in modern telephone transmission systems,[33] and perhaps even expendability of defective units, are a distinct possibility.

As a result of some of these maintenance considerations, it is quite likely that equipment in the future, in addition to being smaller and more compact, will appear more generally in enclosed low cabinets rather than in exposed frames. The administrative control may be from consoles rather than from vertical panels. More attention will be paid to appearance. The appurtenances, such as ladders required for high frames in electromechanical systems, may be eliminated.

Another change in concept which may come with electronics in telephone switching is the form of the power supply. Present-day telephone systems use a centralized single-voltage d-c distribution system with reserve battery. The wide variety of devices and associated voltages, and the need for close regulation in some portions of electronic systems, makes a reliable a-c distribution system with individual power rectifiers at the point of use appear quite attractive. To insure reliability of service, the a-c distribution must be continuous and not dependent directly upon commercial sources.

There is no question but that reliability is imperative if electronic switching systems are to survive among electromechanical systems which have achieved a high degree of reliability over a long period. The device reliability of the first electronic system may not be comparable since some of the components of the electronic switching systems will not be as reliable in their initial applications as the least reliable component in present-day systems. Reliability must be earned and this will probably require considerable effort. Even if initially some devices employed in electronic systems do not measure up to the present high standard which has been set, continuity of high-quality service is a must. It is, therefore, necessary to design a system which will mask the shortcomings of any individual electronic component.[32] As their reliability is proved, an optimum balance will be sought between system redundancy and component quality. Telephone engineers familiar only with the high degree of reliability of present-day apparatus will have to accommodate themselves to the characteristics of new electronic devices.

(*Discussion follows.*)

Discussion

W. H. T. Holden (Pasadena, Calif.): The discussion of common-medium switching systems in this paper appears to be based on the studies made on such systems in the period just preceding World War II. Both time- and frequency-division systems were considered. While Mr. Joel has shown the 2-wire repeater found necessary in these systems in the common medium, the requirements for this were not mentioned in the paper.

It was found that in any common-medium system there is an inherent loss in transmission, due both to impedance mismatch and to the energy absorbed by other terminals in frequency division, and to the necessity of spreading the energy in the sampling interval of time division systems over the entire interval between pulses. This results in substantial losses, reaching as much as 72 decibels in the case of a 2,000-by-2,000 frequency-division array.

Gains of this magnitude are a difficult problem in a 22-type repeater in the range of frequencies around 10 megacycles. The power level needed to supply a level of −6 to the output side is also a problem.

While it might have been possible in theory to supply gain in the individual channels, this would have made the system economically impossible with vacuum-tube amplifiers. It may well be that in the course of time transistor amplifiers will be reduced in cost to the point where this is practicable.

It may also be pointed out that the basic features of switching systems do not seem altered by the introduction of electronic methods. In fact, some system features once used and abandoned may well warrant revival with the better tools available today. The station sender of the Lorimer system is an example of such a device.

A. E. Joel: The two forms of common-media systems together with space-division systems now appear basic to electronic switching systems. No attempt has been made in this paper to evaluate or compare these types. Crosstalk in electronic switching networks as well as inherent losses may impose gain limitations.

The basic differences which occur in electronic switching systems over electromechanical systems is further concentration of the functions. For example, in existing common-control systems per-call memory may be found in locking relays located in such widely dispersed physical requirements as the switching network, trunk circuits, registers, senders, and markers. With the bulk electronic memory, many storage functions associated with calls in progress may be retained in the same compact physical device. The basic requirements for service and the functions which switching systems perform to carry them out have not changed.

Field Experience with the A2A Video System

RAYMOND W. GAST
NONMEMBER AIEE

A NEW video transmission system known as *A2A* has recently been developed for use on local wire channels in television network service. The *A2A* system provides video transmission for frequencies up to 4.5 mc (megacycles) and to distances of approximately 10 miles over balanced cable pairs designed for the purpose. This paper will describe the system from a field point of view, showing typical applications and performance and operating considerations.

The first *A2A* system was installed for field trial in July 1954 and underwent tests for a period of 10 months. This was prototype equipment. Commercial service in New York, N.Y., was initiated with production-type equipment in September 1955 on one studio-transmitter line, followed by eight network-connecting lines in October and November of the same year. Since then, substantial numbers of *A2A* systems have been installed in various cities to provide for growth and to facilitate maintenance of critical lines.

The local video channel forms an important part of the closed-circuit network as used for television broadcasting. *A2A* design is predicated on meeting high-quality performance objectives for an over-all 4,000-mile network which may comprise a number of local circuits as well as intercity facilities.

In the early days of television broadcasting when each station provided its own program material, a signal might originate at a field pickup point, be transmitted to the studio over a short link, and from the studio to the broadcast transmitter over another; these two links would constitute the entire closed-circuit path. With nation-wide networks, circuits have been extended to thousands of miles in length with complex intercity and local facilities operating in tandem. The transmission quality expected on a coast-to-coast circuit excels that which may have been acceptable on the local loops alone a few years ago. Introduction of color has added further exacting transmission requirements to those for black and white. Local video channels constitute only a small part of the network circuit mileage but they form important and critical links in the over-all system. Fig. 1 shows the circuits for a typical network telecast in simplified form. In this particular instance, six local circuits are connected in tandem with the intercity facilities. Most network programs will involve at least three local circuits at the sending end and two at the receiving end.

The makeup of a television network varies from hour to hour according to program demands, and it is not possible to line up or equalize the network on an over-all basis. Each link must be capable of a transmission quality such that when all the necessary links are connected in tandem, the picture will not be appreciably degraded.

Design Considerations

The *A2A* system is designed to use the shielded cable pairs which have been placed extensively for video use in the telephone plant since 1947. Each balanced video pair consists of two 16-gauge wires, polyethylene-insulated and enclosed in a double shield of copper tape. Several versions of video pair have been manufactured which differ slightly in construction but are similar in electrical characteristics. The *A2A* system may

employ any of these shielded video pairs but it is not designed for use with ordinary paper-insulated telephone pairs which have been employed for video to a limited extent in the past.

The circuit lengths over which *A2A* must operate depend on the physical locations of studios and other terminating points, also the locations of telephone buildings which can accommodate repeaters and the available cable routes. In a city, an erratic pattern of terminal and repeater locations is to be expected as illustrated in Fig. 2. The squares represent large studios, master controls, broadcast transmitters, and the operating center for out-of-town networks. There are numerous other studios and pickup points not shown. The circles represent telephone buildings which are suitable for repeater points. The lines indicate principal routes for video cable. Terminal locations are fixed by service demands but there is some choice of routes and of repeater points. Where feasible parallel circuits are assigned in different routes or different cables for added protection of the service.

The circuit lengths range from a fraction of mile to about 10 miles with the majority 1 or 2 miles long. In a large active television center such as New York, local circuits are rearranged, connected, and disconnected with surprising frequency to meet the day-to-day needs of broadcasters and industrial users. Studios, many of which are in leased buildings, may be moved and sometimes change hands from one broadcasting company to another. In addition, there are unpredictable demands for one-time pickup and closed-circuit networks. These requirements are anticipated in the *A2A* system by a variety of amplifiers and cable equalizers which may be assembled in a number of combinations. Portable equipment is available for temporary installations. Both the portable and the rack-mounted equipment is arranged for flexible assignment with cable sections of any length up to the working limit.

Fig. 3 shows a simplified block diagram of a single-link *A2A* circuit where there is approximately 1 mile of cable between the transmitting terminal and the receiving terminal. The circuit is of unity gain with an input of 1 volt peak-to-peak for the composite video signal. The transmitting terminal consists of a cable equalizer which introduces low-frequency loss complementary to the high-frequency loss of a portion of the cable. This is followed by an output amplifier which supplies gain and converts the 75-ohm unbalanced input to a balanced output, the impedance of which matches closely the characteristic impedance of the cable pair. The transmitting terminal has several functions. It effectively isolates the cable pair from the studio equipment and provides a nearly perfect termination for the input signal. Thus it is possible to monitor the signal at the input terminal by means of a very-high-impedance monitoring probe. Secondly, the pre-equalization at the transmitting end of the circuit causes high-frequency components to be transmitted at high level to overcome the cable attenuation losses while the low-frequency components, which are attenuated a lesser amount by the cable, are

reduced to a lower level to prevent excessive modulation or overloading in the amplifiers.

At the receiving terminal the input amplifier again terminates the balanced cable pair, matching its impedance over the entire video band down to very low frequencies. With impedance matching at both ends of the cable, the effects of reflection and interaction are eliminated. Consequently, it is necessary to equalize only for the true loss characteristic of the line and the equalizer units can be provided in various sizes to correct for measured lengths of cable.

The input amplifier has a 75-ohm output impedance. All of the remaining equipment in the receiving terminal is interconnected at this impedance. Beyond the input amplifier the receiving terminal consists of one or more fixed cable equalizers with associated amplifiers, a group of variable equalizers for fine adjustments, and a receiving amplifier which delivers the 1-volt output signal.

A clamper operates in shunt with the 75-ohm path within the receiving terminal as shown in the block diagram. It samples the crest level of each synchronizing pulse of video signal and feeds back at the bridging point a signal which substantially cancels any low-frequency interference or distortion which may have been superimposed during transmission.

The various amplifiers in the system are operated at fixed gains. Small adjustments in the operating level are made by means of an attenuator which is calibrated in 0.5-db (decibel) steps.

The terminals diagrammed in Fig. 3 show unbalanced connections of 75-ohm coaxial type for interconnection with the facilities of broadcasters and industrial users. Optionally these terminals may be arranged for 2-wire balanced connections at 124-ohm impedance. The balanced arrangement is generally used by the telephone company at its own points of interconnection.

A nonrepeatered circuit arranged as shown with flat amplifiers is useful up to about 3.2 miles of cable length. This distance may be increased by substituting other output amplifiers and input amplifiers. The increased range is obtained through an amplifier-to-line network which embodies transformer action over the upper part of the 4.5-mc band. The transformer coupling increases the high-frequency gain so as to overcome losses of the longer cable pair. In practice, the range is increased to about 3.8 miles by substituting the output amplifier with one of the network type. For a still longer cable, the input amplifier also is changed to one of network type.

If the circuit is more than 4¹/₄ miles long, one or more repeaters are inserted to keep the individual cable sections within the limits for a single link. A repeater contains elements found in the terminals, namely, an input amplifier, one or more equalizers with intermediate amplifiers, and an output amplifier which delivers the signal to the succeeding link of cable.

It is seldom possible to lay out a circuit with ideal repeater spacings because of the physical conditions encountered, such as the location of buildings. A practical advantage of *A2A* is its adaptability to irregular repeater spacings and to various cable lengths. The need for this is evident in Fig. 4 which shows examples of actual lines in New York City. *A* and *B*

Fig. 4. Typical A2A lines

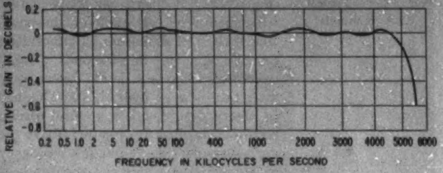

Fig. 5. Over-all gain characteristic of typical 5-mile circuit

are single-link circuits. Line *A* uses the flat amplifiers which have been described. Line *B*, due to its greater length, requires one network-type amplifier at the sending end. Examples *C* and *D* are lines requiring one repeater, and of identical length. The unequal repeater spacing in *D* makes necessary a network-type amplifier for the first cable section. *E* illustrates a 4-mile link which may be operated without a repeater provided two network-type amplifiers are employed, one at each end of the cable. All of these lines have been field-tested successfully and the first four are in commercial service.

An exceptionally long *A2A* line, example *F*, is one of the circuits from a color studio in Brooklyn, N. Y. Theoretically, this line could be designed with only two repeaters instead of three, but here again ideal repeater spacings are not possible. Two of the cable sections are long enough to warrant use of network-type input amplifiers but the equipment shown was selected for the sake of simplicity. There are lines operating in each direction along this route and similar repeaters are employed in all of the circuits.

Performance

The original field trial circuit, 5 miles long with one repeater, was tested over a period of 10 months and confirmed that the design objectives for the system had been realized. After the first commercial circuits were installed on network connections to the New York Television Operating Center and on a studio-transmitter line, their performance was watched critically by the broadcasters and by the telephone company. Aside from a few minor difficulties at first which were traced to faulty components, the performance of these lines in regular service has been most satisfactory, confirming the results of the earlier tests.

The measured over-all gain-versus-frequency characteristic for a representative 5-mile circuit is given in Fig. 5. The residual gain ripples are less than ±0.04 db up to about 4.8 mc. Above this frequency the response rolls off gradually with the 6-db point at about 7 mc. These data were taken with laboratory-type test equipment capable of indicating a difference of $^1/_{100}$ db.

The low-frequency response is plotted down to only 300 cycles. If this curve were extended it would show uniform response down to frequencies below 60 cycles. In the *A2A* system there are no line transformers which could introduce low-frequency distortion.

As mentioned previously, fixed cable equalizers are available in discrete sizes to handle circuits of a variety of lengths. In equalizing a line, values of fixed equalizers are chosen so that the gain at 4.5 mc is brought within ±1.25 db of the low-frequency gain. Precise equalization is accomplished by manually adjusting a group of variable equalizers at the receiving terminal. In this operation, gain is measured relative to that at a reference frequency of 300 kc; this is done at nine specified frequencies while the appropriate equalizers are adjusted. The residual slope across the band is first corrected by setting a cable shape equalizer so that the gain at 4.5 mc equals that at the low reference frequency. Next, the very-low-frequency region is adjusted. Finally, minor deviations within the band are corrected by means of a number of variable equalizers of proper shapes. Altogether, by this procedure ten points in the video band are adjusted to precisely the same relative gain. If the cable sections are long, four additional adjustments are provided making 14 frequency points which may be set precisely. With this equalization method an initial cable distortion of 100 db or more may be reduced to less than 0.05 db. The range of adjustment in the variable equalizers is sufficient to correct deviations on lines up to $6^1/_2$ miles long (120 db of cable slope), with margin for periodic readjustments.

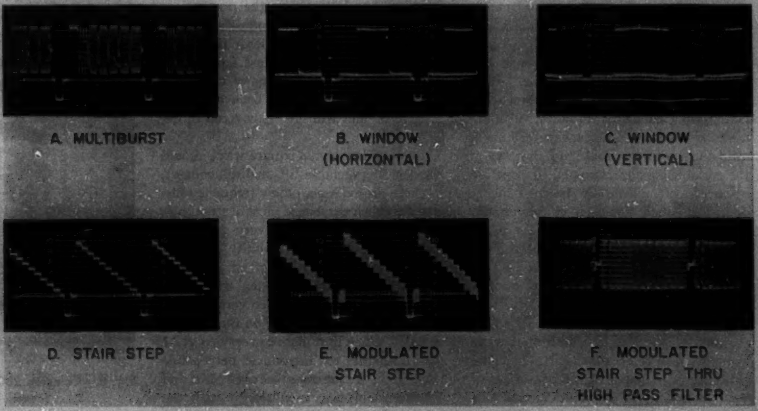

Fig. 6. Test signals over A2A, 9 circuit-miles

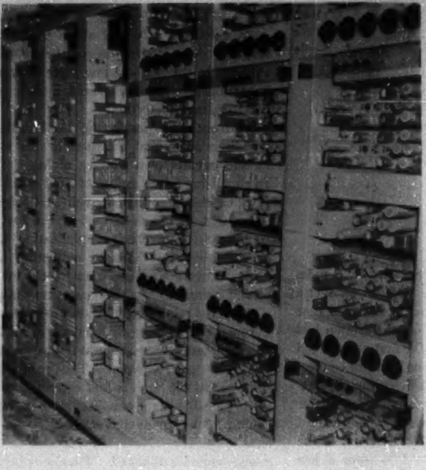

Fig. 7. Typical A2A terminals

On extremely long lines, a second set of variable equalizers is usually added. Such is the case for the previously mentioned 13-mile line which involved an overall cable loss of 238 db at 4.5 mc, corrected by equalization.

The system has proved to be stable in frequency-gain characteristic, the only significant change over a period of time being attributed to the effect of temperature on attenuation of the video cable. With most of the cable underground, this change is a gradual seasonal effect which lags a month or more behind the outside temperature. Based on measurements made over an extended period, the average rate of slope change is approximately 0.15 db per week for a 5-mile line.

Each fixed cable loss equalizer has associated with it a corresponding phase equalizer for correcting the phase distortion in the related length of line. With the appropriate phase equalization associated with each loss equalizer, it is unnecessary to make phase measurements or adjustments in the field. In the case of the variable equalizers no phase correction is necessary. Not only is their phase distortion small but their characteristics above 4.5 mc are such that their phase tends to be complementary to the characteristics being equalized.

Fig. 6 shows test signals photographed after transmission over two $4^{1}/_{2}$-mile circuits in tandem. These are the familiar multiburst, window and stair-step wave forms from a Telechrome portable signal generator.[1] Signals like these are not used for making adjustments in the *A2A* system, but they are convenient for rapidly checking the over-all quality of transmission through the various facilities involved for a network television program.

It is essential, of course, that the oscilloscopes used at various points be alike in performance for wave-form tests to be significant. In this instance, a single high-quality oscilloscope was used, first to set up the signals, and then to observe them over the looped circuits under test. An *A2A* line in normal adjustment will introduce no appreciable change in the multiburst presentation, either as to the relative amplitudes of the white flag and sine-wave bursts or as to their symmetry. A pronounced change in the proportions of the test signal would indicate a probable trouble condition, either in the transmission path or in the test equipment. The effect of various forms of distortion on these test signals has been described elsewhere[2] and will not be covered in detail.

The window-signal square wave should show no appreciable tilt or displacement, as these are evidence of low-frequency distortion which can cause picture streaking. The *A2A* systems shows very good low-frequency response and stability.

High-frequency ringing, if present, would be evident at sudden transitions from black to white, or vice versa, where the transients would show on the window signal. When first placed in service, *A2A* was thought to introduce perceptible ringing at frequencies between 4.0 and 4.5 mc. This was inconsistent with the design theory, and was not supported by subsequent tests. It was found, however, that if the test signal has an abnormally fast rise time (0.1 microsecond), a small overshoot will appear on the square wave after transmission over *A2A*. This will be observed only on a wide-band oscilloscope. The effect is produced above the normal transmission band at a frequency of approximately 5 mc and apparently is due to the phase characteristic in the cutoff region. In the *A2A* system phase equalization is not carried above 4.5 mc inasmuch as the higher frequencies are filtered out by television broadcasting transmitters and thus do not affect home receivers. The spiking effect may be minimized by proper adjustment of rise time in the test signal generator and synchronizing pulse generator.

Differential gain (as checked by the modulated stair-step signal) and differential phase are of special interest because of their effect on the color subcarrier in the National Television Systems Committee color system. The amount of differential gain and phase is, of course, dependent on the number of amplifiers used in each circuit, but does not necessarily add arithmetically when units are placed in tandem. Measurements taken with the *47A* transmission measuring set[3] show

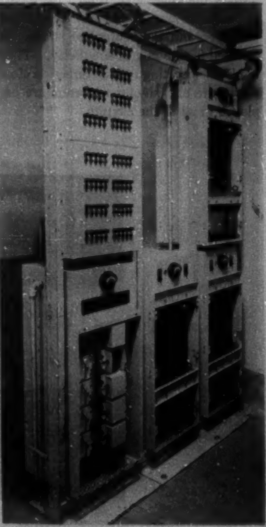

Fig. 8. Common 200-volt d-c power supply (covers removed)

Vol.
Pt. 1
1956

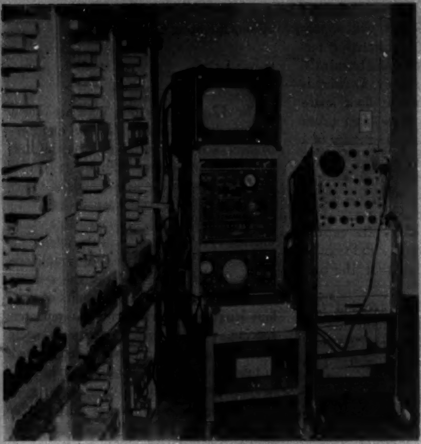

Fig. 9. Typical test equipment

that on a typical *A2A* circuit, differential phase is 0.2 degree or less, and differential gain of about 0.2 db may be expected, for the maximum signal voltage excursion. Measured on a voltage basis, by the modulated stair-step method, the differential gain is less than 5-per-cent white expansion. These values are small fractions of the allowable differential phase and gain, from camera to receiver, in the National Television Systems Committee system.

Signal to Noise

Noise objectives for *A2A* contemplate, as in other aspects of performance, that the local circuit is part of the tandem network connection. By design, the *A2A* line must have a better signal-to-noise margin than is accepted as satisfactory for the over-all network. The effect of random noise on a picture depends on the spectral distribution of the noise across the video band. With appropriate weighting the presently accepted objective for a long network is about 54 db.[4] This is in terms of peak-to-peak signal to weighted rms noise. It includes requirements imposed by color which are somewhat more severe than monochrome. Considering the number and length of local circuits which may be involved, an objective of 65 db was taken as desirable for one local circuit. This is the design figure which determines the allowable length of cable sections in the *A2A* system. Field measurements of weighted random noise are in good agreement with the computed performance.

In field operations, this type of weighted noise measurement is not commonly made. Noise is usually judged by visual observation of picture or by checking the video wave form for thickening of base lines in the blanking interval. Indication of noise by the oscilloscope method depends on the characteristic of the instrument used. For example, a wide-band oscilloscope with flat response exaggerates the effect of noise because it lacks the frequency weighting and also displays noise effects which are outside of the video band.

The *A2A* video system contains numerous safeguards against extraneous noise. Among these are balanced-line transmission, elaborate shielding, and shock mounting of amplifier panels. Wire video transmission, by its very nature, involves the amplification of weak signals at the end of long sections of cable, where the higher frequencies have been attenuated as much as 67 db below 1 volt. Amplifiers handling these low-level signals are susceptible to outside disturbances and require that certain precautions be taken. Noise problems may be avoided by installing the equipment so that it is not subjected to abnormal mechanical vibration, it is not subjected to abnormal acoustical noise, and it is separated a safe distance from possible sources of electrical disturbance. The last consideration includes electric equipment containing make-and-break contacts such as signaling devices, relays, and switches. Normal precautions are also required to bond and ground equipment frameworks and to eliminate differences of potential between the *A2A* ground, the power-line neutral, and the ground used for studio equipment.

Typical Installations

The following will consider typical *A2A* equipment from the point of view of one

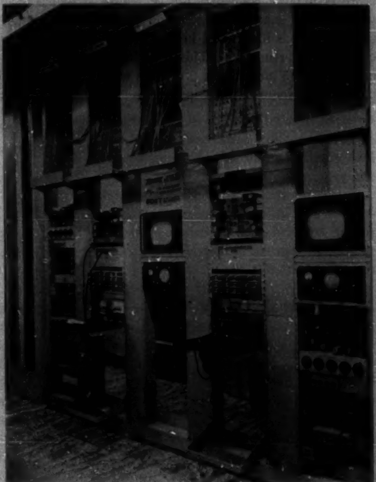

Fig. 10. Jack fields and test positions

planning new installations or having to operate the system. Fig. 7 shows a typical group of terminals as installed at a studio location. The racks are self-supporting, 7-feet high with 19-inch equipment panels. Wiring is enclosed in the vertical rack members which are of duct construction. *A2A* equipment is specially designed for duct-type racks and generally it is not practical to mount the panels on other types of framework. In this illustration the two left-hand bays contain power regulator and alarm panels, and selenium-type rectifier units. The third bay contains six transmitting terminals. At the right are six receiving terminals, two per bay. These facilities should be located within 100 or 200 feet of the broadcaster's jack panel with which they are connected by means of flexible coaxial cables. Room for telephone company equipment may be determined in the early stages of planning for new studios. In established locations, where space is usually at a premium, considerable ingenuity may be called for on the part of the broadcaster and the telephone company to find a suitable location which meets operating requirements.

A2A terminals are also available in portable cabinets. These are convenient when the service is of temporary nature or or where only one or two lines are involved.

The *A2A* system employs small rectifier units which in general supply plate power to an individual receiving terminal, an individual repeater, or up to four transmitting terminals. For locations where there is a large concentration of equipment, use is made of a common power supply such as illustrated in Fig. 8 with cover panels removed. This unit has a capacity of 15 amperes at 200 volts with provision to increase the capacity to 22.5 amperes by adding another rectifier section. A 15-ampere unit will supply power to a total of 22 transmitting terminals and 22 full-size receiving terminals. With a common power supply, a saving is realized in cost and in the floor space occupied. Precautions have been taken in the design to minimize the chance of a service interruption. Should one rectifier unit fail, lose its a-c supply, or require servicing, the remaining units will carry the full load without interruption. In a similar manner sections of the filter capacitor are protected individually and may be replaced during the time that the unit remains in service.

An elaborate array of precision test equipment is provided for circuit line-up, equalization, and maintenance. Some of the typical gear is shown in Fig. 9. This illustrates the need for adequate working space around the terminals. All of the testing preferably is done right at the terminal equipment. Allowance is made for the short coaxial to the studio termination, by substituting an equivalent loop of the same cable during the tests.

Fig. 10 shows a large *A2A* installation in a telephone building indicating the central jack fields and test positions. Here, the high ceilings permit use of 11-foot 6-inch racks. The video cables terminate at the top of the bays where the pairs are connected by flexible patch cords to the assigned equipment. Secondary jacks are placed at working level. Here circuits may be monitored and, in the event of trouble, emergency units may be patched in. The telephone key and lamp panels form part of a communication system which connects with other video locations throughout the city. Some of the test equipment is rack-mounted; the remainder, not shown, is portable. This installation provides terminals for 36 *A2A* circuits serving the New York Television Operating Center.

Conclusions

The *A2A* video system fills a need for a high-quality local wire facility to interconnect television studios, transmitters, and other operating points. It transmits standard, composite signals at video frequencies for distances up to about 10 miles over shielded low-loss cable pairs provided for the purpose in the telephone plant. Unit construction of amplifiers and cable equalizers adapts the system for flexible operation with circuits of various lengths and with irregular repeater spacing. Transmission quality is such that several *A2A* lines may be connected in tandem with intercity facilities in normal network operation.

Once the video cables and *A2A* equipment have been installed, circuit line-up is straightforward and rapid and lines can be rearranged readily to meet changing service demands. Careful planning of *A2A* facilities with particular emphasis on good working space and proper location will facilitate maintenance and assure optimum performance of the system.

Multiunit Neutralizing Transformers

T. F. PALMQUIST
ASSOCIATE MEMBER AIEE

IN RECENT YEARS there has been a large increase in the number of communication, telemetering, pilot-wire relay, and other control circuits required by power utilities in Canada. Service continuity on these circuits is of prime importance, and in many cases neutralizing transformers are required to maintain this continuity and to prevent damage to the circuits or terminal apparatus due to ground potential rise.

Ground potential rise occurs whenever a power-system fault, or lightning, causes current to flow through a power-station grounding structure to earth, the amount of rise being dependent upon the current flow and upon the resistance to ground of the power-station grounding structure. The amount of current flowing to earth through the station grounding structure depends, of course, on the location of the fault in the power system and the type of power system including the station grounding arrangements, transformer impedance and connections, and proximity of other grounded structures. In commonly occurring situations, the resistance to ground of a power-station grounding structure may vary from small fractions of an ohm to several ohms and fault currents impressed on a station ground may vary from a few hundred to many thousands of amperes. In some circumstances, the maximum fault current may be controlled by the insertion of additional impedance in the fault-current path, such as the provision of reactors in the ground connection to wye-connected transformers, thus limiting the ground potential rise.

Increases in the size of generating, transformer, and other power stations has resulted in consequent increases in potentials, which may be applied to communication and control circuits serving a power station at times of fault on the power system. This has necessitated development of neutralizing transformers with increased neutralizing capacity. These neutralizing transformers are usually inserted in the communication or control circuits at the power station concerned and their action, as described further in this paper, prevents excessive currents and voltages from being impressed on the circuits, thus preventing protector operation and possible circuit failure.

In Canada there have been projected circuit requirements of 100 or more circuits terminating in the larger generating stations. Stations with such large circuit requirements are usually major hydro developments, some of which are associated with the St. Lawrence Seaway project.

Previously, multiple installations of single-unit neutralizing transformers were used to provide protection. This, however, increased mounting-space requirements and complicated the wiring arrangements with consequent increases in costs and hazards. Multiunit neutralizing transformers are quite often a reasonable solution to problems of this type as the space requirements are much reduced and the wiring is simplified. Their possible range of rated neutralized voltage is adequate for protection against potential differences which would otherwise exist between the communication or control circuits and ground. Designs for multiunit neutralizing transformers with rated voltages exceeded about 25,000 volts are not as yet available.

Operation of a Neutralizing Transformer

The operation of a neutralizing transformer, in preventing grounding of a communication circuit through its protectors when potentials are applied, is briefly described here for sake of completeness. Fig. 1 illustrates a typical communication circuit serving a power station with a neutralizing transformer in the circuit. A power-circuit fault to ground will cause current to flow through the power-station grounding structure and raise the potential of this ground with respect to grounds at remote points. This potential will be applied to the communication circuit between the power-station protector ground and the central-office protector ground and without supplementary protection may cause these protectors to operate and perhaps permanently ground or damage the communication circuit. With the application of a neutralizing transformer as shown in Fig. 1, the power-station ground-potential rise is applied to the primary winding of this transformer and the resulting current flow induces an equal and opposite potential in the secondary windings. As the secondary windings are connected in series with the communication circuit, this induced voltage will reduce the potential applied across the protector blocks to zero under theoretically ideal conditions and, practically, to less than the operating rating of these protector blocks. Essentially, the neutralizing transformer applies a potential across the circuit protectors which is equal and opposite to that applied to the protectors by ground potential rise.

Description of Typical Multiunit Neutralizing Transformer

Multiunit neutralizing transformers may be obtained in any size from about two to about 101 pairs. The primary and secondary windings of the transformer described in this paper are wound parallel on the transformer core, the primary winding consisting of no. 8 American Wire Gauge polyvinyl chloride (PVC) insulated wire and the secondary consisting of a 26-pair inside-wire cable with 22-gauge conductors insulated with PVC, a core wrapping of two layers of Mylar tape each 2 mils in thickness, and with a PVC outer jacket. Transformers of sizes larger than 101 pairs are somewhat impractical as the cable becomes quite large and difficult to wind and there is increased leakage reactance due to generally increased primary and secondary winding separations. As the designs are similar, a 26-pair transformer has been selected as typical and the descriptions and test data included in this paper will refer to this size of transformer. The voltage rating of this transformer is 5,000 volts at 60 cycles.

Figs. 2 and 3 show the 26-pair transformer; in Fig. 2 its case is removed. This transformer weighs approximately 4,400 pounds. Figs. 4–6 show three views of the transformer mounted on channel beams supported by two poles. As the transformer in this installation was not grounded at its location, the transformer base was placed about 8 feet above the ground. This was done to prevent the

installation being touched from the ground as this would be hazardous at times of fault in the power system. In most installations the neutralizing transformer is grounded at the location at which it is installed, thus removing this hazard and the necessity for special protective measures.

Figs. 5 and 6 illustrate the complexity of wiring and the large mounting-space requirements where a number of single-unit neutralizing transformers are placed at one location. Protective coverings may be required for the neutralizing transformers where they are connected in series if there will be differences in potential between transformer cases or between transformer cases and ground. These coverings may also be required for frame terminations should there be large differences in potential between the various terminations concerned, such as where all connections to a neutralizing transformer terminate on a frame. Special care must be taken in such instances to provide adequate dielectric strength between termination mountings and to provide means of short-circuiting the transformer primary winding to eliminate potential differences between the transformer terminations when the cover is removed for maintenance or other purposes. In the illustrations the covers were made from plexiglass. Complex installations of this type are eliminated by the use of multiunit neutralizing transformers.

Types of Circuits as They Affect Neutralizing Transformer Design

Of the various types of circuits normally in use at the power station, such as telemetering, pilot-wire relay, load control, and voice, only those employing grounded direct current will effect neutralizing transformer design. All of these services may employ grounded direct current; however, the continuous current in any conductor of a leased facility is limited to 0.35 ampere. The longitudinal direct currents will increase the flux density and tend to saturate the transformer, depending on the a-c excitation of the core. This will decrease the impedance of the primary winding and thus increase the remnant voltage as additional current will flow through the primary circuit. An increase in the size of the transformer core, alterations

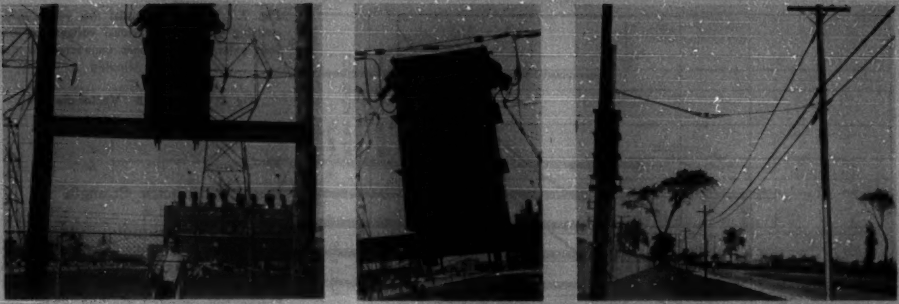

Fig. 4 (above across). Multiunit neutralizing transformer installation

to the type of steel core, or variations in wire size and number of turns may often be introduced advantageously in transformer design to minimize this problem.

Primary Winding External Impedance and Remnant Voltage

The exciting current in the primary winding of the neutralizing transformers must flow through the connection to the remote ground. The remnant or unneutralized voltage is the vector sum of the voltage drops across the remote ground resistance, the connecting conductor between the power-station ground and the remote ground, the primary resistance, and the leakage reactance of the transformer. The primary resistance and leakage reactance are, of course, determined by the transformer construction. Thus the resistance of the remote ground-protector lead wire and the resistance to ground of the remote ground electrode must be sufficiently small that the remnant voltage resulting from the voltage drop across these resistances will not be excessive.

The remnant voltage of the 26-pair 5,000-volt multiunit neutralizing transformer with 0- and with 35-ohm external impedance in series with the primary winding, is shown in Fig. 7. A vector diagram of the various voltages and currents involved in determining the remnant voltage is shown in Fig. 8. The remnant voltage is, of course, applied longitudinally to a communication facility.

In the experience of the author's company, the types of terminal equipment generally used will not be adversely affected by a remnant voltage of 150 volts.

Impulse Dielectric Strength Requirements

To prevent lightning damage to a neutralizing transformer, it is necessary to provide a lightning arrester bridged across the primary winding. The impulse dielectric strength between the windings and between the windings and the transformer core must exceed the impulse rating of the lightning arrester. Distribution-type lightning arresters are normally used with unit-type neutralizing transformers as the use of more expensive arresters is not warranted by the cost of the neutralizing transformer installation. For this reason it is necessary to design unit-type neutralizing transformers with large impulse dielectric strengths. The use of station-type arresters offers economic advantages in the construction of multiunit neutralizing transformers as their impulse ratings are lower than the distribution-type lightning arresters, which permits lower transformer dielectric strengths for a given rms voltage rating and thus economies in construction.

The transformer described in this paper withstood the impulse tests specified in American Standards Association or National Electrical Manufacturers Association standards for a 5,000-volt distribution transformer.

Transmission Losses

The insertion loss of a typical 26-pair 5,000-volt 60-cycle multiunit neutralizing transformer is shown in Fig. 9 and the test arrangement used is shown in Fig. 10. The d-c loop resistance of the secondary windings was 57 ohms for this transformer.

Crosstalk

Typical voice - frequency crosstalk values for a 26-pair 5,000-volt 60-cycle multiunit neutralizing transformer are shown in Fig. 11. The crosstalk was measured using a multifrequency source of disturbing power and a noise measuring set.. The difference in level in decibels between disturbing and disturbed circuits may be determined by subtracting

the measured crosstalk in decibels from 90 decibels.

The crosstalk results, evaluated in terms of expected crosstalk on standard communication cables, are quite satisfactory.

Leakage Reactance, Winding Resistance, and Capacitance Between Primary and Secondary Windings

The 26-pair 5,000-volt 60-cycle neutralizing transformer selected as typical had the following characteristics:

Leakage inductance = 1.7 millihenrys
Primary resistance = 1.3 ohms
Secondary loop resistance = 57 ohms
Average capacitance between primary and secondary windings = 0.04 microfarad

Experience and Operating Results

There are six existing installations of 26-pair multiunit neutralizing transformers in Canada and a number of future installations are planned. There have been no difficulties in operation or maintenance to date.

Recent Developments in 4-Wire Switching of Long-Distance Telephone Circuits

IMRE MOLNAR
MEMBER AIEE

WITH the rapid expansion of dial operation on toll telephone calls since the end of the last war, automatic switching machines have taken over many of the functions previously performed by operators on convenient toll switchboards. One of the results of this mechanization, or perhaps one of the prerequisites for its economic justification, was that a varying number of toll circuit links, from one to eight, may be used to build up a connection between two terminal points. It should be understood that the number of links may vary within these limits on different occasions, even between the same two end points and on the same type of calls, at the discretion of the machines and governed automatically by the prevailing traffic conditions. Furthermore, in addition to the maximum of eight links in a toll connection, there will usually be at least one more link at each end, connecting the toll offices with the local offices serving the calling and called subscribers, and there will always be one more link at each end connecting the subscriber's telephone with its local office. This situation differs considerably from that which existed with previously used methods of toll switching; it introduces new transmission problems requiring new engineering solutions.

The Application of 2-Wire Circuits

Except in a few special applications such as power-line carrier and ground-return rural lines, the subscriber's telephone instrument is always connected by two metallic conductors to its local telephone office. Likewise, one pair of conductors is used to connect the local with the toll office, even though it may be equipped with loading coils and amplifiers.

This pattern was followed in the beginning of toll telephone operation, and a pair of metallic conductors, or a single conductor with ground return, was used for interurban communications. The inherent loss of metallic circuits set a limit to the distance over which telephone traffic was feasible, even with heavy-gauge conductors and artificial loading. Spanning of long distances required the use of active voice repeaters.

Until recently all amplifiers of practical importance were unidirectional devices: the amplified speech currents were passed only in one direction. To obtain 2-directional or duplex transmission, two amplifiers, one for each direction, had to be combined into one repeater, and inserted into the 2-wire line at the point where gain was needed. As there was only one pair of input and one pair of output terminals available for the repeater, the input of each amplifier had to be in some way connected to the output of its mate. Due to the gain of the amplifiers, circulating currents established with both amplifiers in series would generate oscillation (or "singing") in the repeater, unless special circuit provisions were made to separate electrically the input of one branch from the output of the other branch. Such a device is the hybrid bridge circuit. While the hybrid circuit is well known to transmission engineers its essential principles should nevertheless be recapitulated, since it forms the core of the 4-wire switching problem.

The Hybrid Circuit

A 2-wire repeater is shown schematically in Fig. 1. Z represents the impedance of the external line as seen from the terminals, and N is a network which should simulate the line impedance as closely as possible in the transmitted frequency range. A is the input impedance and B the output impedance of the amplifiers. The eastward and westward directions of transmission might have different impedance characteristics.

The repeater is symmetrical about the center line between east and west; therefore it is sufficient to analyze one half by itself. This is shown in Fig. 2, in a simplified form (the elements of a Wheatstone bridge circuit can be readily recognized). If the impedances *1* and *2* of the hybrid coil are equal and $Z=N$, and if a generator is then connected in series with B, there will be no voltage across A: that is, the input of one amplifier is effectively isolated from the output of the other, and the repeater will inherently be stable in the frequency range where the impedance balance applies. If we assume, for simplicity's sake, that all windings of the hybrid are equal, that $Z=N=600$ ohms, B will be 1,200 ohms for maximum power transfer. Only half of the energy delivered by the amplifier to windings *3,4* is passed on the line Z; the other half is dissipated in N.

If a generator is connected in series with Z instead of B, energy is received from the line. Assume the impedance of A is one half the impedance of N, 300 ohms. The impedance B reflected into winding *1* is one-fourth of B or 300 ohms, due to the 2-to-1 ratio of windings *3* and *4* to *1*. Therefore half of the voltage across the input terminals of the repeater will appear across the input terminals to the amplifier, if there is no current through winding *2* and network N. Indeed, the voltage across winding *2* will be the same as across winding *1*, but in opposite phase, and since the voltage across winding *1* is the same as the voltage across A, the terminals of N are at equal potential, and thus no energy is dissipated in N. Half of the energy delivered from Z to the repeater is passed on the amplifier input A, and half dissipated in the opposing amplifier output B. Again, 300 ohms for A results in maximum power transfer.

Return Loss

Now, obviously, satisfactory stability of the repeater depends on the degree of equality between line impedance and balancing network impedance. If there is any impedance mismatch, current will be reflected from one amplifier output into the input of the mate amplifier. The reflected current will travel back to the distant end of the circuit where the original current started out, and if the propagation time is appreciable, it may result in undesirable echo. If the total gain in the echo path exceeds the total loss of the echo path, the circuit may even become unstable and "sing." The impedance mismatch may be expressed by a quantity called "return loss," which is the ratio,

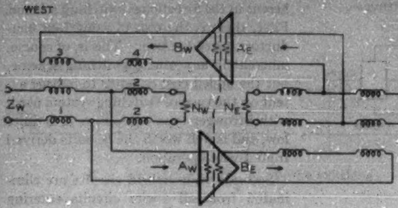

Fig. 1. 2-wire repeater

in decibels, of the amount of power reflected into the hybrid coil to the amount which goes on toward the listener. As line and network impedances vary with frequency, the return losses vary likewise, but for practical purposes a single weighted figure of the return losses within the transmission frequency band is used.

Terminating Impedance

If the repeater is inserted at an intermediate point along a toll line, the networks have to match the toll line impedances only, as seen from the point of insertion of the repeater. While a perfect match is hardly obtainable, the degree of approximation is in a way only a matter of cost. The situation is different with repeaters at the end points of the line, say the "west" terminal in Fig. 1. Here the network N_W should match the impedance of Z_W of the local line. Now, the impedance of this local circuit may vary over a wide range. The circuit is usually composed of three sections in tandem: cabling and equipment impedances in the toll office, the connecting trunk between toll and local office, and the line between the local office and the telephone instrument.

The toll office impedance has little effect in small offices, while in large installations there may be a substantial difference between the different paths a call can take through the switching equipment. The connecting trunk may have practically zero impedance if the local and toll offices are in the same building, or may have 1,500 ohms or more if long and with loading. The telephone line may likewise be very short, and its impedance virtually equal to the impedance of the telephone instrument, or it may be long, and its impedance equal to the characteristic impedance of the telephone line. Moreover, two or more telephones might be connected across the line in a conference, or the line might be entirely open after the subscriber disconnected. With such an extremely wide range and large number of variables, a single value must be assigned to N, which obviously must be a compromise between the differing conditions.

Connecting trunks which are electrically long and have a reasonably stable impedance structure represent a fairly constant impedance, independent of the length of the telephone line terminating them. However, a toll circuit must usually be switched to a variety of connecting trunks, and the network should balance with any of these. Later on, we will see that there are means available to assign individual precision networks for each trunk, or to employ impedance compensation of the connecting trunks. But even then, unless the trunks are long, the effect of the variations in the terminating telephone line prevents a very high terminal return loss. One way to improve the terminal return loss of a connection is to insert a pad between the toll line and the connecting trunk, since the pad will tend to equalize the impedance of the connecting trunk as seen from the toll-line repeater. A 2-db (decibel) pad brings about a 4-db improvement in the terminal net loss, which is usually sufficient in toll offices which have no equipment and cabling irregularities.

Through Switching

When two toll lines are interconnected in a toll office to form a multilink connection, another potential source of impedance mismatch has been created. In such case, referring again to Fig. 1, the west end of one circuit is connected to the east end of the other, and the two compromise networks will be facing each other, with the switching equipment and office cabling interposed. However, as a rule, the match in this case is better than in the terminating condition described in the previous paragraphs.

Because of the undesirable effects of mismatch in the hybrids, the number of repeaters which a 2-wire connection may contain is limited; furthermore, the loss of each section cannot be less than a certain minimum value. The limitations are even more severe on the number and characteristics of intermediate toll switching offices taking part in a built-up connection.

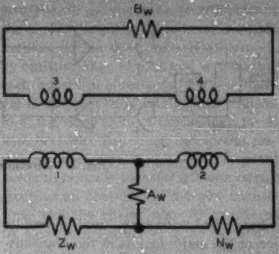

Fig. 2. Schematic half-repeater

Four-Wire Circuits

If the repeater shown in Fig. 1 is cut open between the east and west hybrids, and then the hybrids moved to the east and west terminals of the toll circuit and interconnected by a circuit containing four conductors, with amplifiers inserted along the route where needed, points of return loss are eliminated except at the two end points. This is, of course, the principle of 4-wire transmission, whether over physical conductors or over separate unidirectional carrier channels. However, as long as switching between toll circuits in toll offices is carried out over two wires, both the incoming and the outgoing toll circuits must be reduced through hybrid circuits from four wires to two wires at each intermediate switching office, and the restrictions as to the number and characteristics of such offices in a built-up connection apply as in the foregoing.

The ideal situation, of course, would be to have unidirectional 4-wire circuits in all transmission paths, local and toll, including the telephone line, up to the telephone transmitter and receiver. As a matter of fact, the telephone instrument is a 4-wire device, where the input speech and the output sound are, apart from the circuit arrangement in the telephone, independent of each other. Now, for economic reasons only 2-wire circuits are used for telephone lines; therefore the essentially 4-wire circuit of transmitter and receiver is reduced by an arrangement which is in many respects similar to the one we have discussed for the 2-wire repeater. Telephone instruments have their echo problems just like repeaters; the transmitter current reflected into the receiver

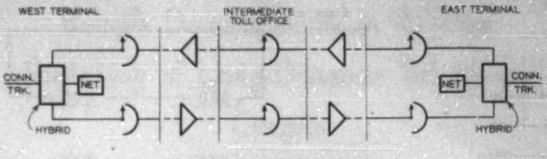

Fig. 3. Directional 4-wire switching

is here called "side tone," and represents one of the major factors in the transmission performance of telephones. The telephone transmitter is a sort of amplifier, but due to the peculiar design and method of use of the telephone handset, there is no acoustical coupling of practical importance between transmitter and receiver so telephones are highly stable in spite of the very imperfect impedance balance of their 4-wire termination. Loudspeaking telephones, on the other hand, with a considerable amount of acoustic coupling between speaker and microphone are unstable unless the return loss in the 2-wire to 4-wire circuit is high. Two factors contribute to the return loss: the precision of impedance match, and the loss in the acoustic path.

Four-Wire Toll Switching

Whether the transmission engineer's millennium of a complete 4-wire system up to and including the subscriber's telephone will ever materialize in commercial telephone systems is still obscure at the present, although it has been done occasionally for special applications. However, as the great majority of long-distance toll traffic is being carried over 4-wire circuits, the majority of built-up connections require interconnection of 4-wire circuits at intermediate switching points. The next logical step is, therefore, the elimination of intermediate 2-wire switching, with its undesirable transmission characteristics, as far as is economically feasible.

As will be recalled, we have derived a 4-wire circuit from a 2-wire repeater, such as shown in Fig. 1, by a vertical cut through the center and displacing the two ends to the extreme west and east terminals, respectively. The two terminals were interconnected by four leads, representing a 4-wire toll circuit. The arrangement is then a 4-wire circuit from end to end, unless in intermediate 2-wire switching offices the four wires have to be compressed to two, and again expanded into four. If, on the other hand, the connection should be carried over four physical conductors through intermediate offices, a true 4-wire circuit would be maintained from end to end, with all points of return loss automatically eliminated, except, of course, at the two terminal points, where the 2-wire connecting trunks are joined.

The Directional Switching Scheme

The directional switching scheme is shown in Fig. 3. To distinguish this arrangement from the network switching method to be described later, it will be referred to hereafter as "directional switching," since a separate pair of leads is used throughout for each direction of speech transmission.

The outstanding features of 4-wire switching are, first, the elimination of impedance mismatch at intermediate points by the elimination of hybrids; second, an added gain of about 6.5 db at each such point, also due to the elimination of two hybrid circuits, which, as we have seen before, consume over 3 db at each coil.

Another feature is the inclusion of a hybrid coil at each 2-wire connecting trunk. Since this coil is always assigned to a certain connecting trunk, the balancing network can precisely match the impedance of the associated trunk line, thus greatly improving the terminal net loss. Though this is an important advantage, it cannot always be fully exploited in practice. If the connecting trunk is short, its impedance depends to some degree on the impedance of the terminating telephone circuit; therefore some compromise still has to be made in the value of the balancing network, which sets a limit on the maximum attainable reduction of terminal net loss. High-loss connecting trunks can be fairly accurately balanced, and some of the available excess gain in the 4-wire terminal can be used to counteract the loss in these trunks; however, the tendency is towards reducing the loss within the connecting trunks themselves. Nevertheless, the possibility of more precision in the balancing of connecting trunks is a definite advantage of 4-wire switching.

There are certain disadvantages inherent in the directional switching scheme. First, there is the cost of using four conductors instead of two. This is, of course, inherent in any 4-wire switching scheme, but the added cost depends to a large extent on the type of switching system used; with Strowger-type equipment it is quite low, and is well worth the benefits derived from 4-wire operation.

Second, while hybrid circuits are eliminated from all 4-wire circuits entering the toll office, a hybrid circuit must be provided for every 2-wire circuit, be it a 2-wire toll line or a connecting trunk or an operator trunk. Admittedly, there may be some large toll switching centers that have to take care of a volume of through switching traffic which is large compared with the volume of traffic terminating locally; in such cases the number of calls switched on a 4-wire basis, not requiring a hybrid, may be larger than the number of calls switched to 2-wire, which do require a hybrid. However, such applications are the exception rather than the rule; usually the local terminating traffic predominates. Therefore, in most cases a greater number of hybrid circuits must be provided with the directional switching scheme than with a scheme where hybrids are associated with 4-wire toll circuits only.

Third, care must be taken that the transmission level in the office cabling and switching equipment shall be about the same in both branches of the 4-wire circuit; otherwise crosstalk might occur. This precludes the use of pads between hybrid and trunk, or hybrid and balancing network—a measure which would otherwise help to improve the terminal return loss; if such pads were provided, the input and output speech levels would be substantially different at the hybrid, and even more so at the switching equipment. With the directional switching scheme all pads are located within the toll-line terminal trunk, away from the switching equipment. Even so, due to the loss through the hybrid circuit, there is a difference of about 6 db between the transmission levels in the two branches, at the switches.

Fourth, inasmuch as we have obtained a true 4-wire circuit with separate paths for each direction of transmission, some special arrangement is needed if we wish to intervene at some intermediate point. For instance, if a switchboard operator with a conventional telephone set arranged for 2-wire connections is needed to be bridged across the 4-wire circuit, a rather complex applique is required. The situation is similar with talking circuits for test personnel.

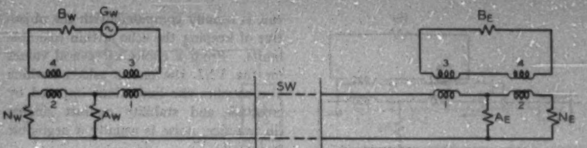

Fig. 4. 2-wire switching

The Network Switching Scheme

The scheme to be described is free from the last three handicaps indicated in the foregoing, but shares all the advantages mentioned, with some more added.

Let us, for a moment, consider 2-wire switching as shown in Fig. 4. G_W is a voice source located in the west terminal. Energy is transmitted towards the east terminal. If the balance is perfect, half the energy from G_W, which is passed through the transformer, is dissipated in N_W, half flows towards A_E (half of the latter is dissipated in B_E) and will be amplified there, but nothing is dissipated in A_W, which means that there will be no echo produced. In practice, however, perfect balancing is impossible due to the switching equipment *SW*, and part of the energy generated at G_W will be reflected back to A_W. For instance, as an extreme case, if one of the leads in *SW* is open, no energy flows to the east, two thirds of the energy passed through the west hybrid is dissipated in N_W and one third in A_W (assuming the same 2-to-1 impedance ratio as before).

As the next step, remove both balancing networks, N_W and N_E, and, instead, connect the terminals as shown in the lower part of Fig. 5. A few facts are immediately apparent. First, assuming that the "line" and "net" paths in *SW* are identical, the bridge on the west side is in perfect balance (if we consider the impedance A_E to have been sliced in two, and one half, together with east winding *2*, moved to the left-hand side of the bridge, Fig. 6). Under such conditions, there will be no potential difference across A_W, and no energy dissipated there. Perfect balance will prevail, as long as any change in the line path is accompanied by an identical change in the net path, and vice versa.

Second, we may now omit A_W altogether, and follow the current flow created by G_W through windings *1* and *2* of the west hybrid coil. If we follow the arrows, we will discover that due to the reversal in the net path, the current converges in opposite phase upon impedance *A*. The east hybrid in this condition is nonreactive, and no energy will be dissipated in A_E. Therefore, all energy delivered by the west hybrid will reach the east amplifier input A_E; this results, in addition to freedom from echo, in a 6-db gain of the circuit as compared with the 2-wire case shown in Fig. 4.

Third, assume B_W to be 1,200 ohms, A_E to be 300 ohms, 1-to-1 transformer ratios throughout, no energy dissipated in transformers and leads, slice A_E into two parts (600 ohms each), and disregard impedances A_W and B_E since they receive no energy. Examining the circuit, we find that generator impedance B_W and load impedance (600 ohms plus 600 ohms) are equal, therefore maximum power transfer conditions are established.

Fourth, in the 4-wire switching scheme being discussed, energy is transferred in both directions over two paralleled 2-wire paths, each path carrying one half of the energy. Therefore, the speech power level will be the same in both paths at any point in the system.

The arrangement just described, employing the network switching principle, is, for obvious reasons, called the "tail-eating" 4-wire switching system. As already explained in the foregoing description, it offers a 6-db gain over 2-wire switching, which is only slightly (less than 1/2 db) lower than attainable with the directional arrangement, due to the inherent transformer losses in the hybrids. Furthermore, it offers the same degree of stability and freedom from echo as the directional scheme, as long as the impedances in the line and net paths are equal. Actually, the circuit is rather insensitive to impedance mismatch; for instance, should one of the four conductors become completely open, there is still about 30-db return loss maintained (versus infinite loss in perfect balance condition).

The tail-eating arrangement is superior to directional switching in that only 4-wire circuits must be equipped with hybrids (which they usually are anyhow), and 2-wire circuits may remain as they are, without adding a hybrid. In contrast to directional switching, the transmission power levels are the same in both pairs of the 4-wire circuit, so there is no crosstalk problem within the quad. Furthermore, by omitting the net path and terminating each hybrid in a network, 2-wire switching is automatically established. Therefore, the same circuits can be used for 2-wire or 4-wire switching; no special provision (other than to open the net path) needs to be made to insert a 2-wire circuit (such as an operator) in a 4-wire connection, and the circuit may be monitored by a direct bridge across either the line or the net pair. The switching circuits of the tail-eating scheme are simpler than those used with directional switching, which simplifies maintenance, and also provides for greater flexibility for possible future changes.

The tail-eating scheme has all the advantages of directional switching. It was mentioned that its inherent gain is about 1/2 db less; however, since there is an excess gain in 4-wire switching anyhow, the pad values are so selected that the transmission losses of both arrangements are the same. This will be explained in more detail later. The tail-eating method also permits the use of precision or compromise networks assigned to individual 2-wire trunks (see Fig. 7), and the presence of pads in both the line and net branches provides for superior terminal return losses.

The only point of caution needed with the tail-eating system is to insure as close symmetry as possible between line and net paths through the switching equipment and central office cabling. In the design of circuits and equipment the symmetry is perfect, limited only by the manufacturing tolerances of the same components. Symmetry in cabling is insured by the use of quadded cables for the 4-wire circuits, and consistent paralleling of the branches in all cases.

Transmission Losses of Toll Circuits

So that we may more fully understand the switching operations employed in a 4-wire switching system, let us divert briefly from our main subject and consider some of the transmission problems involved in long-distance telephone operations.

During recent years the long-distance toll plant has been built up to a point where at present most of the traffic is carried over repeatered voice circuits, carrier channels, and radio links (with the last two media by far predominating) instead of by metallic circuits only, as in the past. It can be safely predicted that the preponderance of derived channels will increase in the future at an even more

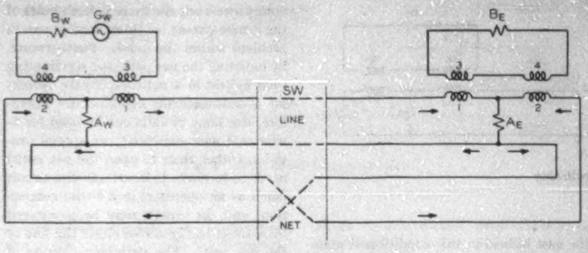

Fig. 5. Tail-eating scheme

Fig. 6. Tail-eating bridge

rapid rate. Now one of the significant results of this expansion is that, in general, there is more gain available in the toll circuits, in spite of their length, than is necessary to secure the desirable transmission level at their output. The obvious approach in such a situation would be to operate all circuits at zero loss, since, in addition to providing the same level of transmission as obtained by direct interconnection of the terminals, it would make transmission independent of the number of circuits connected in tandem when a circuit is built up between the same two end points over devious alternate routes.

Of course, if the circuits could be operated at a gain instead of zero loss, some of the loss of the connecting trunk between the toll office and the local telephone office, as well as the loss inherent in the line between the local telephone instrument and the local office, could be compensated for. Unfortunately, up to date it has been found impossible to operate long toll circuits on a zero-loss basis. The gain of repeatered voice-frequency circuits is limited by noise and by stability limits at hybrid points, as well as by crosstalk and echo, while carrier circuits must be operated at a finite loss because the last two factors are still appreciable when the distances are long, even though the velocity of propagation approaches the velocity of light.

One of the facts learned from years of operation of transmission circuits is that if two or more circuits are switched together for a through connection, the total loss of the connection can be lower than the sum of the losses of the individual circuits when they are used by themselves. The explanation for this is that the factors mentioned in the preceding paragraph do not increase in proportion to the length of the connection or to the number of circuits connected in tandem. This is particularly true if 4-wire switching is employed at the intermediate points, because then it is only at the terminating points that the 4-wire circuit is reduced to 2-wire; the factor of return loss is eliminated in all but the two terminating offices.

The lowest practicable loss of a toll circuit is the loss required by the foregoing limiting factors when the circuit is switched to another circuit at both ends; it is called "via net loss" (VNL). Experience has shown that on electrically long circuits, echo is the most difficult factor to control, so the permissible VNL of a circuit is usually computed with the objective of keeping the echo within tolerable limits. From a choice of several values for the VNL the one is selected which also satisfies the limitations imposed by crosstalk and stability against singing (in practice, noise is usually a negligible factor).

The computation of the VNL is based on probability considerations, taking into account a large number of contributing elements, such as: length of the circuit and velocity or propagation, the expected precision of balance at both terminals and its statistical distribution, the deviation of the circuit losses from their nominal value and its statistical distribution, the amount of echo tolerated by the telephone users and the statistical distribution of the tolerance, the availability of echo suppressors, and the amount of added loss at the terminating points of the connection. This method of computation can be used only with 4-wire circuits; the VNL of 2-wire circuits is established by engineering judgment based on experience.

Typical VNL values of facilities in use at the present may range from 0.5 db for 50 miles of short-haul carrier to 2.4 db for 200 miles of loaded voice-frequency 4-wire cable, with 500 miles of coaxial carrier about halfway between these two.

The VNL of a built-up connection may be obtained by adding the VNL of the individual sections together, provided that 4-wire switching is used at the intermediate switching points. Intermediate points using 2-wire switching are added potential sources of echo and singing, and it is expected that such connections built up through such points can be worked at the VNL permissible with 4-wire switching intermediate points, only if the average balance (return loss) in each of such offices is 27 db or better. If the balance is lower, the VNL of the circuit terminating there must be correspondingly increased, for instance, by 0.2 db if the balance is only 23 db.

The ultimate objective, of course, is that the VNL of a built-up connection

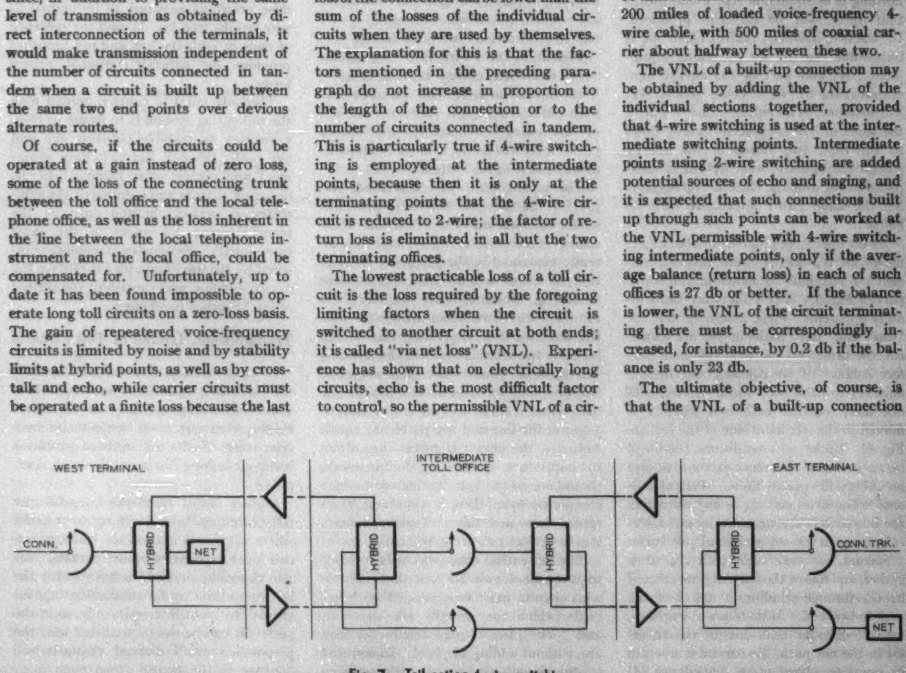

Fig. 7. Tail-eating 4-wire switching

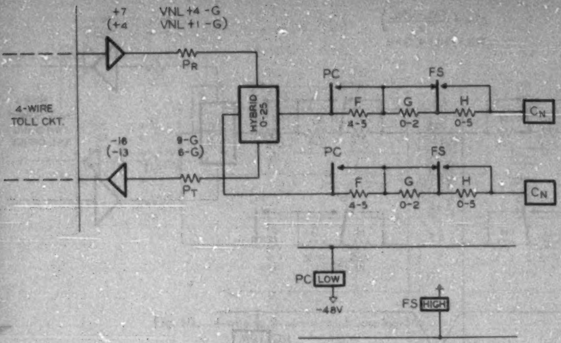

Fig. 8. Idle condition

P_R = receiving pad
P_T = transmitting pad
C_N = compromise net

should be as near as practicable to the VNL of a direct circuit between the same two terminating points. At the present, or even in the foreseeable future, this ideal cannot be achieved. In general, telephone users are likely to object only if the transmission level between the same two telephones varies by more than 5 db on different occasions; therefore the immediate objective is to keep the VNL of a connection within this limit, regardless of which of the possible alternate routes the call may take.

At the present time, we are still quite a way from even this immediate objective. For instance, it may be practicable to maintain circuit stability to such a degree that the net loss of a 4-link connection will be within a range of about 9 db in 96 per cent of the cases, if the variations in losses of the individual circuits are combined on a statistical basis. In an 8-link connection the variation in losses would be about 40 per cent greater. In addition to these, there will be a variation in the average values of the VNL of a connection, dependent on the number and the VNL of the links used for the different alternate routes. Fortunately, only a minor fraction of all calls will use four links in a connection, and the probability of eight links is one in several millions.

Switching of Losses at Terminating Points

In the preceding section we have discussed the via net loss of a connection—that is, the minimum loss which must be maintained due to the inherent characteristics of the links used and regardless of the disposition of the connection at the switching office. The minimum permissible loss is more than VNL when the circuit is used between two telephone instruments, because the same toll circuit must be used under a great variety of telephone loop conditions in the local telephone networks served by the terminating toll offices, and the balancing network in the terminating hybrid has to be a compromise over a wide range of possible impedance values. Therefore, the local line will hardly, if ever, be perfectly balanced, and to maintain echo and stability within satisfactory bounds the over-all circuit loss must be increased. The minimum loss in terminated conditions is called "terminal net loss" (TNL), and at the present state of the art and with the best available facilities TNL = VNL + 4 db, that is, an increment of 2 db at each end.

A toll circuit will, at any given moment, be found in one of the following conditions: 1. It may be idle. 2. It may be switched to a 4-wire toll circuit or to any toll circuit with terminal repeater. 3. It may be switched to a 2-wire toll circuit without terminal repeater or to a local connecting trunk with a high inherent loss. 4. It may be switched to an ordinary local connecting trunk. (In addition, the circuit may be switched through an operator, but this condition will be excluded from the present discussion.) Furthermore, the toll circuit may be a 4-wire circuit (or a circuit having a terminal repeater) or it may be a 2-wire circuit; and it may terminate at the distant end in an office with 4-wire switching or in an office with 2-wire switching. For the present, we will assume that the near end terminates in an office with 4-wire switching facilities. Whether the distant office is of a 4-wire or a 2-wire type may have some bearing on the VNL of the circuit, but not on the pad values used for switching in the near-end office.

In the following we will discuss the ways in which these different states are provided for in the Automatic Electric Company's new *FW-1* Intertoll Switching System. To illustrate the transmission relations, numerical values will be assigned to the various elements. For instance, assume that the transmission level at the output of the demodulator is 7 db above the level of the entrance point of a toll connecting trunk at the other end of the toll circuit link, and that the input level to the modulator is 16 db below the level of the entrance point of a toll connecting trunk in this office. Therefore the total gain of a circuit link from modulator input to demodulator output at the far end is 23 db. These +7- and −16-db levels are accepted standards for modern transmission facilities, though higher total gains (26 db) can occasionally be found, with corresponding changes in the output levels. Older transmission facilities with a total gain of 17 db are still in extensive use with +4- and −13-db levels, respectively. The corresponding values for the transmitting and receiving pads are shown in the figures in parenthesis.

In the discussion assume that the connecting trunk plants are such that TNL = VNL + 4 db is satisfactory. The added loss is derived at each end by a 2-db value of the *G* pad. While at the present time not all connecting trunk plants can assure this value for TNL, an effort is being made to improve the return losses, with this objective. Where the plant cannot be operated at TNL = VNL + 4 db, toll connections may need to have, for the time being, a higher TNL: for instance, VNL + 8 db if the terminal return loss is degraded at each end by 4 db. The 4-db impairment in the terminal return loss can be compensated for by an added loss of 2 db in the transmission path at each end; thus the value of TNL = VNL + 8 db. As the value of the *G* pad in the *FW-1* system is 4 − (TNL − VNL)/2 db, *G* will be 0 db for circuits which must be operated at a TNL = VNL + 8. It is a surprising peculiarity of 4-wire switching that the value of a switching pad is actually decreased when a higher TNL is required and that the additional loss is derived from the trans-

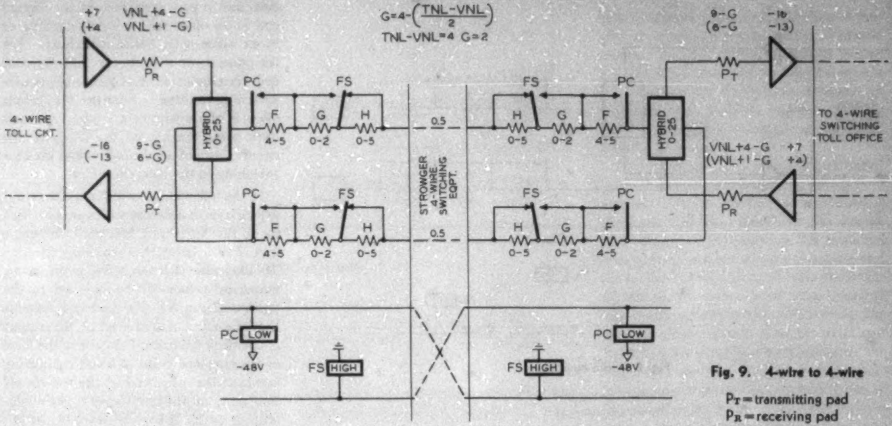

Fig. 9. 4-wire to 4-wire

P_T = transmitting pad
P_R = receiving pad

mitting and receiving pads. The examination of the circuits later in this paper will reveal the reason for this. However, as will also be demonstrated, the terminal return loss of 4-wire switching is inherently high, and therefore, in general, a TNL = VNL + 4 db may be assumed for most applications.

We will further assume that there is only about 0.25-db loss in a hybrid coil in the 4-wire to 4-wire state due to the losses in the associated wiring and the usual transformer losses; the loss is about 3.5 db in the 4-wire state because, in addition to the 0.25 db mentioned, half the input energy is dissipated in the balancing network. Losses in the central-office cabling and the switching equipment may amount to 0.5 db.

1. IDLE STATE (FIG. 8)

When a 4-wire circuit (or a 2-wire circuit having terminal repeaters in the toll office) is not in use, the line and network terminals of the hybrid circuit are terminated in identical networks, and theoretically an infinite terminal return loss is obtained. The 5-db loss inserted between each of these terminals and the networks further improves the balance of the hybrid. When the circuit is seized from the distant end and the connection is built up in the office, the terminating network of the line side is passed on at each step until the terminal of another toll circuit (which will be discussed in the next two cases) or a local telephone is reached, and a very high return loss is continually maintained. When the called telephone answers, the terminating network at the hybrid line terminals is replaced by the impedance of the connecting trunk plus local line terminated by the telephone instrument. The switching details will be described later.

Two-wire toll lines without terminal repeaters have no hybrid circuit and therefore create no problem. They are, however, terminated in the same type of network for the sake of standardization and to improve the stability of any repeater which might be located near the terminal.

2. CONNECTION TO 4-WIRE CIRCUITS (FIG. 9)

When a 4-wire circuit is switched through to another 4-wire circuit, the line terminals of both circuits and the network terminals of both circuits are interconnected as previously explained. The speech energy divides evenly over both paths and then recombines in the correct phase through the hybrid transformers. The only loss inherent in this arrangement is due to the office cabling and equipment; in addition, of course, to the ordinary transformer losses in the hybrids, to a nominal 1-db total, as already pointed out. As the output of a repeater demodulator is at a +7-db level and the input to a repeater modulator should be at a −16-db level, a minimum of 23-db loss must be inserted into both paths. Part of this loss is assigned to the receiving pad, part to the transmitting pad in the repeaters, and the balance (less 1 db) to the switching pads of both trunk circuits.

One of the interesting characteristics of 4-wire switching, as distinguished from 2-wire switching, is that in a through-switch condition, it requires an added loss, while with 2-wire switching in this condition, loss is eliminated as far as possible. This difference occurs because with 2-wire switching half of the available energy is dissipated in the balancing networks, while in 4-wire switching practically all available energy is transmitted from one circuit to the other, thus gaining twice 3 db. Now, assuming that TNL = VNL + 2, with 2-wire switching twice 2 db must be removed from the circuit in the through switch state, while with 4-wire switching (with an excess gain of twice 3 db) twice 1-db loss must be added to switch through with the same VNL as in the 2-wire case. In local terminating condition the TNL-VNL in a 2-wire office is supplied by a 2-db pad or a minimum 2-db trunk loss, while in a 4-wire office it is supplied by the hybrid coil. Since the hybrid loss is 1 db higher than 2 db, the output level of a repeater in a 4-wire office must be 1 db higher than in a 2-wire office, and this difference is then eliminated by the switching pads in a through switch condition.

When two 4-wire circuits are connected together, both *FS* relays operate over the d-c paths, while the *PC* relays remain unoperated due to the high series resistance. The function of the *FS* relay is twofold: it extends the four conductors through the automatic switching equipment, and it replaces the *H* pads by the *G* pads, thus increasing the loss by 1.5 db.

The statement made earlier that the input level to the modulator should be at a −16-db level must be now slightly

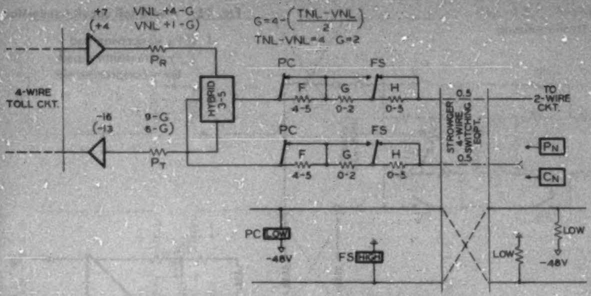

Fig. 10. **4-wire to 2-wire or high loss local**

C_N=compromise net

qualified. In a through-switch condition the input level to the modulator should actually be $-(16+\text{VNL})$ db, and the loss in the through-switch path should be $23+\text{VNL}$ db. The values, for the receiving pad P_R and the transmitting pad P_T are so chosen that, together with the switching pads, this amount of loss is obtained, and that the relation $\text{TNL}=\text{VNL}+2$, can also be maintained, as will be shown under case 4.

3. Connection to 2-Wire Circuits (Fig. 10)

When a 4-wire circuit is to be connected to a 2-wire circuit without terminal repeater, it is desirable to improve transmission by utilizing some of the surplus gain available in the 4-wire circuit. Having no terminal repeater, there is no excess gain available in the 2-wire circuit, so there is no purpose in providing pads and switching relays in the 2-wire terminal. The extra gain is derived in the 4-wire terminal instead by cutting out pads *F* and *H*, and inserting pad *G*. Both relays *FS* and *PC* are operated through resistors in the 2-wire terminal. The loss in the connection up to the 2-wire line is $\text{VNL}+1$ db. The additional nominal 1 db is caused by the loss in the hybrid coil, exchange cabling, and switching equipment. It would be possible to compensate for these and to switch the connection with VNL only; however, it is not considered worth while to introduce an additional condition in the pad switching, and special measures to increase the return loss of the hybrid circuit, for such a nominal gain. The balancing network for the hybrid circuit in the 4-wire terminal is supplied from the 2-wire terminal over the net conductors. As a rule, having perfect symmetry between line and network leads, a standard compromise network is sufficient to provide adequate return loss in the hybrid circuit. Should in some cases the structure of the 2-wire circuit cause difficulties, the circuit as shown is arranged for a precision network to balance out the 2-wire line.

The same arrangement may also be used to compensate to some extent for high losses in connecting trunks, by transferring excess gain from the 4-wire terminal. From the transmission engineer's point of view, there is no difference between a 2-wire voice-frequency toll circuit and a high-loss toll-connecting trunk. While the present objective is to keep connecting-trunk losses below 5–6 db, plans are being made to design such trunks in the future on a $\text{VNL}+2$ db basis, or even for VNL where an intermediate switching point in the connecting trunk is involved.

As ordinary 2-wire circuits without terminal repeaters are not equipped with hybrids or pads, they are directly interconnected by the switching equipment, and there is nothing special to describe or to illustrate. Since there is no gain available anywhere, the loss of the through-switch connection will be the sum of the TNL's of both individual links.

4. Connection to a Local Trunk (Fig. 11)

Terminating a 4-wire circuit locally through an *FW-1* 4-wire toll office is fundamentally the same as terminating it through a 2-wire toll office, because the network leads are not extended unless a high-loss connecting trunk is used as was the case in item 3. In a 2-wire office, $\text{TNL}=\text{VNL}+4$ db, and the extra 4-db loss is supplied either by 2-db switching pads at each end of the connection, or by 2-db fixed pads in the connecting trunks, if they have less than 2-db loss. The same relation $(\text{TNL}=\text{VNL}+4)$ applies to a 4-wire office. Because the network leads are not extended, there is no control potential available to operate relays *FS* and *PC*. Pads *F* and *H* provide the loss required to obtain the required TNL.

The local connecting trunk is balanced by a compromise network, incorporated into the 4-wire trunk terminal. Because of the facilities available in the 4-wire switching system, there is altogether 10-db loss between the compromise network and the network terminals of the hybrid,

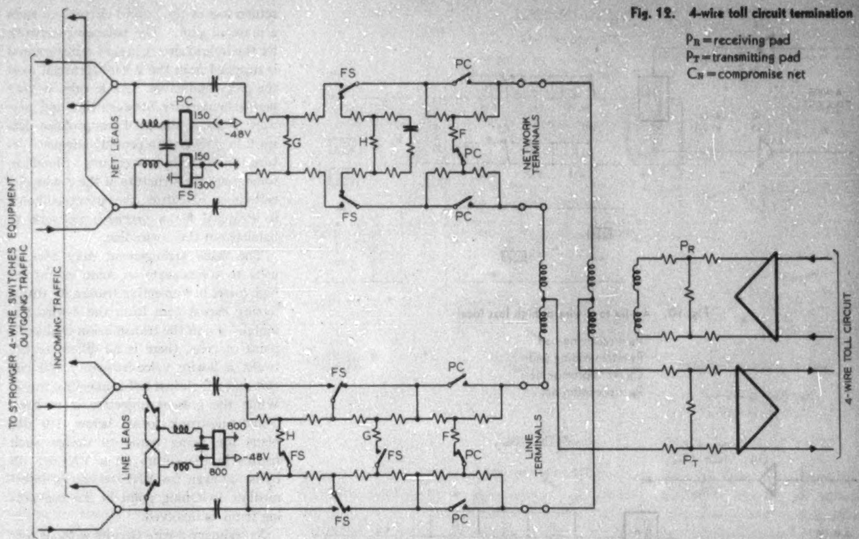

Fig. 12. 4-wire toll circuit termination

P_R = receiving pad
P_T = transmitting pad
C_N = compromise net

and between the line terminals of the hybrid and the connecting trunk. Through such an arrangement a very high terminal-return loss is obtainable which is superior to the conditions prevailing in conventional 2-wire-switching offices where only a 2-db pad is inserted between the hybrid and the connecting trunk.

An ordinary 2-wire circuit is directly connected to a local trunk and there is likewise nothing special to discuss. The TNL of such a connection will simply be the inherent loss of the 2-wire toll circuit.

Four-Wire Circuit Termination (Fig. 12)

In preceding sections, the transmission principles of the *FW-1* intertoll switching system with 4-wire switching were described. Some of the pertinent operations will be explained in the following.

All such operations are carried out over the two net leads, after they are extended through the automatic switching equipment. If a connection is to be extended on a 4-wire basis, line pairs and the net pairs of the two circuits are tied together directly without any attachments. As may be seen from Fig. 12, the line leads are interconnected straight, while there is a reversal between the net leads, to obtain the correct phase relation in the hybrid circuit.

Experience indicates that for stable and noise-free transmission it is advisable to pass a small amount of direct current through all transmission leads of the switching equipment. The reversal of the net leads automatically establishes a d-c potential difference, while for the line leads the d-c circuit is reversed on one (outgoing) end only, without reversing the voice transmission path. The d-c portion of the line leads is used for various switching functions not pertaining to the present subject, and at the same time maintains about 30 milliamperes of current in each lead at all times.

The conditions under which relays *FS* and *PC* are to operate were discussed previously. Relay *FS* will always operate when a connection is to be made through the switching equipment on a 4-wire basis. In its unoperated position, *FS* terminates the network side of the hybrid in a compromise network, while in the operated position it extends the network terminals through the switching equipment. When operated, *FS* replaces the *H* pads by the *G* pads. The only function of the *PC* relay is to cut out the *F* pads in its operated position.

All circuits which may provide 4-wire transmission, such as cases 2 and 3, must have negative 48-volt potential on the winding of the *PC* relay. Under such condition the *FS* relays at both ends of the connection can operate and establish the 4-wire path through the switching equipment. If the 48-volt potential is absent, the connection is made on a 2-wire basis, and the network side of the hybrid is terminated in the compromise network. A variable ground strap changes the resistance of the *FS* relay from a high to a low value; if the resistance is high, the *PC* relay at the opposite end of the connection cannot operate. This is the condition on a 4-wire to 4-wire connection, described in case 2. The *FS* relay must have a low resistance if it is used in a 2-wire circuit that includes the balancing network for the opposite terminal, as described in case 3. The low resistance of *FS* will then permit operation of relay *PC* in the opposite 4-wire terminal. (As already mentioned, in 2-wire circuits with the *FS* and *PC* relays, ordinary resistors may be substituted to control the relays in the opposite terminal.)

It will be noted from this circuit that the line and net conductors are perfectly symmetrical, and since this symmetry is inherent in the central-office cabling and in the physical and electrical layout of the switching equipment, no special measures need be taken in the central-office equipment to obtain a high terminal-return loss even when the connection is made on a 2-wire basis. Quadded switchboard cables are used for the line and net

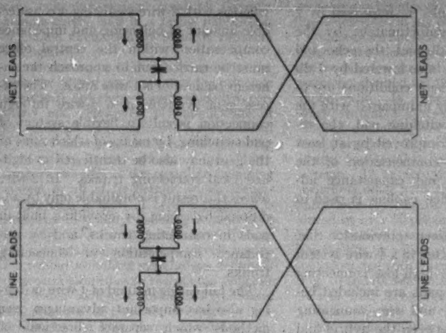

Fig. 13. A-c-d-c phasing circuit

conductors, and these conductors consistently follow identical paths, even where tie connections are made to intermediate equipment. Furthermore, the values for the control relays were so chosen that in a 4-wire to 4-wire connection the same amount of direct current passes through the net conductors as through the line conductors; therefore, a high degree of symmetry is also maintained in the bridging inductive impedances and in the contact resistance of the switching equipment. To keep contact resistances low, precious-metal relay contacts and silver-inlaid switch contacts are used throughout the transmission circuits. When the low-resistance option for *FS* is used, the current through the net conductor is somewhat increased; however, in this state no talking current is passing through the net circuit, and minute variations of the bridging impedance in the net circuit (due to a change in d-c saturation) are inconsequential.

When a call between two 4-wire circuits is originated by an operator within the office, both of these circuits are reached through their terminals assigned for outgoing traffic. In such a connection an additional reversal of the net leads is required, as well as a reversal of the direct current without simultaneously reversing voice transmission in the line leads. The circuit employed for this purpose is shown in Fig. 13. There are two separate transformers for the two sets of leads, connected in such a way as to maintain d-c continuity. The poling of the transformer in the net circuit is such that there is no reversal in phase of the voice transmission. The physical reversal of the conductors creates, then, the required reversal of both d-c and voice-current paths. The poling of the transformer in the line circuit is such that there is a reversal in phase of the voice transmission. The physical reversal of the conductors, then, creates the required reversal of the d-c path and restores the voice current to its proper phase.

Probably the most outstanding advantage of the *FW-1* intertoll switching system over more usual 4-wire switching systems is the simplicity with which 4-wire paths are established and, conversely, that in the absence of a 4-wire path the arrangement automatically returns to a conventional 2-wire state, with better than normal return-loss characteristics. As has been shown, the 4-wire state is contingent on the operation of the *FS* relay, which can take place only if a control potential is extended from the opposite terminal over one of the net conductors. Therefore, a 2-wire state is retained if the opposite terminal is not arranged to extend the control potential; or if the intermediate switching equipment is not arranged to extend the net leads; or if the connecting path is open due to some trouble condition. In other words, the 2-wire state exists in all cases unless the conditions for the 4-wire state are positively established (for instance, if an operator or test personnel intervene in a 4-wire connection, the net leads are simply disrupted and the connection automatically reduces itself to a 2-wire state, with the correct transmission level for ordinary telephone sets). Further, the *FW-1* system permits the use of identical circuits for 2-wire and 4-wire offices, simply omitting in the former case the additional equipment needed for 4-wire operation.

Toll Offices With 2-Wire Switching

Before the development of toll offices employing 4-wire switching, toll calls were extended at intermediate as well as terminating points by using the two wires of the talking leads only. At intermediate points the line terminals of the two hybrids were interconnected over two wires, and the network terminals were closed by compromise networks. At end points the line output of the terminating hybrid was extended over two wires to the local connecting trunk. Due to the relatively low terminal-return loss of the hybrid circuit, the inherent gain of modern 4-wire circuits could not be fully used, and an artificial loss had to be inserted between the hybrid output and the connecting trunk. Since in a through-switch state somewhat lower losses are permissible than in the terminating state, the artificial loss was removed for through connections in 2-wire offices which were arranged for pad switching, and multiswitch connections were established at VNL.

Nevertheless, each intermediate 2-wire office in a multilink connection represented a potential source of echo and instability, due to the low return loss at each hybrid circuit, whereas, in a 4-wire intermediate office, echo paths are automatically eliminated. Therefore, 2-wire offices could not be substituted for 4-wire offices, without an increase of the VNL, unless the return loss at each hybrid point could substantially be increased.

Low return loss is due to unbalance between the office equipment and wiring and the balancing network in the hybrid circuit. The average return loss of a typical 2-wire office, free of equipment and wiring errors, is about 14 db, and unless the average return loss can be raised to at least 27 db, trunks terminating in a 2-wire switching office must be operated at a higher VNL than when there are 4-wire offices at both ends. To achieve such high value of return loss in 2-wire offices, the length of inside cable must be limited, large-gauge cable conductors used, the capacitances of different cable conductors adjusted to a uniform value, and the compromise networks compensated for the impedance of the office cabling and equipment.

Four-wire switching equipment using network switching arrangement automatically eliminates return loss at a relatively small increase in equipment over 2-wire switching. Even for smaller offices it is advisable to investigate whether it is not preferable to provide 4-wire switching rather than expend considerable amount of labor and material needed to improve the return loss in 2-wire offices to a point where their stability may approach that of a 4-wire office. Further, it should also be considered that at each expansion of the office, the new equipment must similarly be balanced.

It has been shown that in a 4-wire office, part of the gain available in the 4-wire circuit may be transferred to passive 2-wire lines or high-loss connecting trunks, thereby improving the over-all transmission of many toll connections. A transmission improvement on high-loss trunks may also be obtained in a 2-wire office, if the switching pad, ordinarily only used for local terminating calls, is eliminated entirely. The removal of the switching pad and its control equipment may also reduce the cost of such toll switching offices. However, assuming that TNL = VNL + 4 as before, some substitute must be found to replace the 2-db losses at each end, which were previously supplied by the switching pads.

Two mutually exclusive conditions may now be considered. The first case involves connecting trunks to local offices in the same building as the toll offices (or in the immediate vicinity) so that the trunk loss is less than 2 db. The second case involves connecting trunks having more than 2-db loss. Now, if a 2-db fixed pad is added to every trunk which belongs to the first group, the transmission status of this group remains exactly the same as it was with the previous switching pad arrangement. Since the transmission loss of a trunk in the second group is more than 2 db, no substitute for the switching pad is needed. Transmission over these trunks is improved by 2 db at each end; unfortunately, by the omission of the 2-db pad, the echo and singing margins are also lowered by 4 db at each end. If these conditions are to remain substantially unimpaired with the omission of the switching pad, the return loss must be improved by at least 4 db. Impedance compensation of the connecting trunks and capacitance adjustment of the office cabling is used to bring this about.

It has been shown previously that means are incorporated in a 4-wire system to transfer gain to high-loss connecting trunks; and since pads are included between the hybrid and the connecting trunk, as well as between the hybrid and the compromise network, adequate terminal return loss can be obtained in the 4-wire system without any further artifice of impedance compensation and capacitance adjustment.

Summary

A new 4-wire switching telephone system has been developed, incorporating the tail-eating, or network switching, principle of operation in its transmission paths. Four-wire switching of telephone calls has the advantage over 2-wire operation that a very high degree of stability and freedom from echo are automatically obtainable on built-up connections, whereas with 2-wire switching a considerable amount of balancing and impedance compensation within the central office must be carried out to approach the inherent balance of a 4-wire office. The excess gain available in a 4-wire through connection permits a flexible system of pad switching, by means of which some of the gain may also be transferred to high-loss local connecting trunks. In 2-wire offices this result is obtainable only by additional balancing, by providing built-in pads in connecting trunks, and by impedance compensation of connecting trunks.

The tail-eating method of 4-wire switching also has important advantages over methods which separate directions of transmission. It eliminates the need for hybrid circuits in local connecting trunks; it permits simplification of the switching circuits; it permits the use of the same circuits for 4-wire as well as 2-wire switching systems; it automatically provides 2-wire operation in every case where the 4-wire control conditions are not established; it permits the use of compromise balances and provides for an efficient system of pad switching while still maintaining equal transmission-power levels in both paths through the switching equipment; and it permits operators or test personnel to intervene, using conventional telephone circuits.

Discussion

J. W. Emling (Bell Telephone Laboratories, Inc., New York, N. Y.): Dr. Molnar presents an interesting discussion of the transmission problems of toll switching but the paper would have been enhanced by references to prior publications on the subject, particularly since much of the material has been so adequately covered by elementary texts on communications and in papers.[1–6]

It would be unfortunate if the impression were gained from the title that the network switching scheme is new. While the application is undoubtedly new in some of its details, the basic scheme is not particularly novel. For example, a patent granted in 1923 describes the "line-to-line and net-to-net," or tail-eating, method of interconnection in some detail.[7] The same general scheme has also been used in some European countries for a number of years.

The advantages of 4-wire switching as compared to 2-wire are well known. The principal item of interest raised by the paper concerns the merits of different types of 4-wire switching. As indicated by the author, the directional switching and network switching arrangements are in some ways alike but also each has its own peculiar advantages. In Bell System applications of 4-wire switching, the directional switching method has been found preferable because of the complete absence of reflection on through switches, the smaller number of hybrid coils required, and the facility with which precision networks can be associated with 2-wire connecting trunks.

Under other circumstances, it is possible that the network switching method would be advantageous although the bases for some of the claimed advantages are not altogether obvious. In this connection it is to be regretted that the author did not explain further the reason why a 30-db return loss is obtained with one of the wires completely open.

Imre Molnar: The first paper quoted by Mr. Emling (reference 1) describes, in 1944, a crossbar toll switching system which is now considered as obsolete. There is about one page devoted to the transmission features of this system, which has no similarity and is irrelevant to the subject matter of my paper.

The second set of papers quoted (references 2–5 of the discussion) describes the nation-wide toll switching plan and a more contemporary crossbar toll switching system. The subject of transmission is likewise contained within about one page and is restricted to generalities.

The Huntley paper (see reference 6 of the discussion) gives an excellent outline of the transmission problems of the toll trunk plans, while the transmission problems treated in my paper concern mainly central-office switching equipment designed around the tail-eating principle. Mr. Huntley was not concerned with 4-wire switching at all, and only in one-half column he summarizes the problems encountered with 2-wire switching. These problems, as a side issue, were also further elaborated and brought up to date in my paper.

Personally, I could not find any elementary or advanced text covering the principle of 4-wire switching in general or the tail-eating principle in particular, other than a German text describing the directional 4-

wire switching systems used by German manufacturers, and in a house publication of limited circulation by Siemens Brothers of England.

I would regret it if anyone would infer from the title of my paper that the principle of network switching is new, which it is certainly not. However, my application of this principle as a substitute for directional 4-wire switching within the framework of the transmission plan adopted for North America, as well as the complete switching system in all of its details, which accomplishes this, is new. I believe that this is sufficient to qualify the subject matter of my paper as a recent development, just as the perennial papers on new developments in crossbar switching systems are definitely of general interest even though the principle of crossbar switching considerably predates the principle of network switching. Incidently, to the best of my knowledge tail-eating systems have not been employed in Europe. There are installations in operation in Australia, South Africa, and Canada which employ tail-eating 4-wire switching, but the transmission objective and the switching principles are very different from those described in my paper.

While there may be some specific applications where directional switching would be preferable, for general applications the advantages claimed for the latter do not seem to be valid. In a properly designed network switching system the reflections on through switching are absent for all practical purposes. The number of hybrid coils is very considerably less with the tail-eating scheme. In an actual application of a toll switching office with about 3,000 trunk terminations the number of hybrids was reduced by over 50 per cent as compared with the directional switching scheme. As to the facility by which precision networks can be associated with 2-wire connecting trunks, Fig. 10 and its description in the text demonstrates that it can with equal facility be done by this new switching system.

Mr. Emling concurs with me that 4-wire switching is superior to 2-wire switching, but unfortunately there is also a widespread impression in the telephone field that 2-wire switching can be made equivalent, with reasonable effort and at a reasonable cost to 4-wire switching in almost any application. I hope that my paper will help to clarify this, and at the same time point out the method by which a system superior to 2-wire switching can be obtained without the cost penalty of more conventional 4-wire switching methods.

The conditions with one of the wires open can be visualized by adding the symmetrical half of the windings (as in Fig. 1) to Fig. 5, and opening up, say, the upper line lead between the no. *1* windings of the east and west hybrids. Assuming that the west terminal is the sending end, practically all energy will now flow to A_E through no. *2* west winding, the continuing net lead and the intact line lead. A small amount of energy will also leak through to A_W because there will be a difference in the respective potentials across the no. *1* and *2* coils of the west hybrid, due to the difference in the nonreactive voltage drops through these windings. The power ratio between A_W and A_E is in the order of 30 db, but this value will vary in practice, dependent on the design of the hybrid and the degree of symmetry of the elements used in the connection.

The Fused Silicon Rectifier

HERBERT W. HENKELS
ASSOCIATE MEMBER AIEE

IN THE past year or two, the culmination of intensive efforts in the development of silicon materials and devices has been the introduction of practical silicon rectifiers to the electrical industry. The widespread use of such rectifiers may be expected in the coming years. At the moment, there appears to be no competitor in the range of operating temperatures below 200 C (degrees centigrade).

Silicon rectifiers can be made by techniques characterized by: (1) a diffusion operation; (2) an evaporation operation; (3) a junction-pulling operation; and (4) a fusion operation. The fusion technique of making rectifiers can be further divided into that employing a wire electrode in the operation (fused-wire diodes) or that using flat solder preforms. It is possible that silicon rectifiers can be produced by a few additional methods, but these are in the research stage of development. All of the four methods of producing rectifiers have been tried successfully; all have certain advantages and disadvantages. Thus, method 1 makes the volume production of *p-n* junctions easy, but subsequent sectioning, etching, and lead attachment somewhat troublesome. Method 2 again permits the large-scale production of *p-n* junctions, but etching and lead attachment are somewhat difficult. The third method is capable of producing the most perfect *p-n* junctions with resulting high-voltage characteristics, but slicing and sectioning problems can cause rather poor forward-drop characteristics. The ultimate limit on the degree of perfection of *p-n* junctions made in large-scale production by the fusion method is lower than that of pulled *p-n* junctions and probably lower than that which may be attained at some future date in diffused junctions. However, very good fused junctions can be prepared and other processing can be made quite simple so that from an over-all economic standpoint the fused junction rectifier is very attractive. Both the fusion techniques employing wires or solder preforms are discussed in this paper.

There are two principal theories of rectifier operation; one based upon a model in which the asymmetry in resistance characteristic arises from the differences in magnitudes of quasi-equilibrium field and diffusion currents, in two directions of conduction, and the other based on a model in which the asymmetry arises from differences in nonequilibrium diffusion currents in both forward and reverse directions.

The first theory, a modification of that enunciated in somewhat different forms by Mott,[1] Schottky and Spenke,[2] and Davydov,[3] describes a field current which is limited by the electron depletion of a dipole region between a semiconductor and counterelectrode contact. The original theory was designed for metal semiconductor contacts and has not been employed in the silicon and germanium *p-n* junction cases of recent interest. However, if the field-limited case is considered for a junction of equal carrier density *p*- and *n*-type materials, Appendix I, the reverse current depends as given in equation 1 upon the semiconductor properties.

$$i=6.19\times10^{-28}n_i(\mu_p+\mu_n)(N_A)^{1/2}(V_{DT}+V)^{1/2} \quad (1)$$

where

i = current density, amperes per square centimeter (cm²)
n_i = intrinsic carrier number density, 1 per cubic centimeter (cm³)
μ_p, μ_n = mobilities of holes and electrons, respectively, cm² per volt-second
N_A = acceptor (or donor) number density, 1 per cm³
V_{DT} = inner contact potential, volts
V = applied voltage, volts

The second theory, that of Shockley,[4] describes a reverse current limited by a

Paper 56-975, recommended by the AIEE Metallic Rectifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 1–5, 1956. Manuscript submitted June 14, 1956; made available for printing August 21, 1956.

HERBERT W. HENKELS is with Westinghouse Electric Corporation, Youngwood, Pa.

The author acknowledges the contributions of J. Lasco, H. Camp, T. Lawson, J. Pappas, and J. Fortier, and expresses thanks to Dr. S. J. Angello, under whose guidance the program was carried out.

diffusion current in the bulk of the semiconductor near the *p-n* junction and depends on the semiconductor properties and constants as given in equation 2.

$$i=2.37\times10^{-27}n_i^2T^{1/2}\left[\frac{\mu_p^{1/2}\mu_n\rho_n}{\tau_p^{1/2}}+\frac{\mu_n^{1/2}\mu_p\rho_p}{\tau_n^{1/2}}\right] \quad (2)$$

with additional symbols defined:

T = absolute temperature, degrees Kelvin (K)

τ_n, τ_p = lifetimes of electrons and holes, respectively, microseconds (μsec)

ρ_n, ρ_p = resistivity of *n*- and *p*-type materials, respectively, ohm-centimeters (ohm-cm)

The quantity n_i is obtained from equation 3

$$n_i^2=AT^3\exp\left(\frac{-E_G}{kT}\right) \quad (3)$$

where previously undefined symbols are

E_G = intrinsic energy gap in the semiconductor, electron-volts

k = Boltzmann's constant, electron-volts per K

A = factor describing density of states in conduction and valence bands (see Table XI)

The current predicted by equation 1 is much larger than that by equation 2. The former equation should hold only when lifetimes are very small, the latter when lifetimes are such that the diffusion lengths defined as $(D\tau)^{1/2}$ or $(kT\mu\tau)^{1/2}$, where D is the diffusion constant of the carrier under consideration, are considerably larger than the extension of the dipole region at the *p-n* junction. The general expression for current through a *p-n* junction with arbitrary values of τ in the semiconductors has not been worked out.

Both theories are concerned only with rectification across a contact between infinite planes of semiconductors; consequently, in the theoretical expressions the potential within the semiconductors in the presence of the dipole at the *p-n* junction is simplified and edge-surface effects are neglected. Since the extension of the counterelectrode junction is much larger than the thickness of the dipole region, there is no appreciable error in the method of calculating potential. However, the parameters in the junctions may have values at the surfaces different from those in the bulk of the semiconductor. Variations in mobilities and resistivities may be neglected in comparison with variations of E_G and τ. Important effects on resistivity of surface changes in E_G have not been noted in bulk silicon semiconductors, but the value of τ at silicon surfaces may vary radically from that in the bulk materials. The principal reason for including the quasi-equilibrium junction theory, equation 1, is to show the limiting case of very small lifetimes.

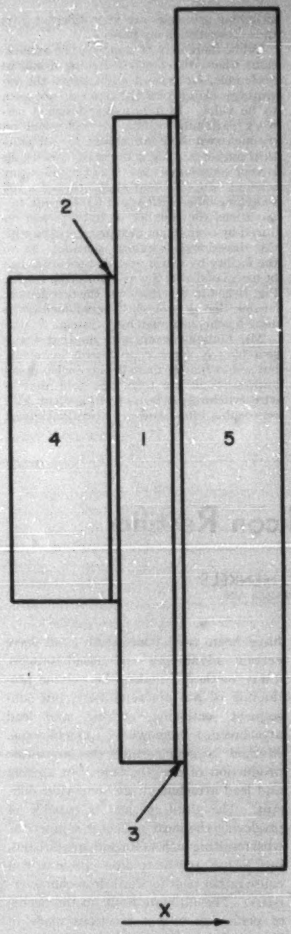

Fig. 1. Rectifier cell components

The quasi-equilibrium theory predicts a forward current which varies as given in equation 4 at low voltage and approaches asymptotically a linear dependence on voltage at high voltage, the slope depending on the bulk conductance of the semiconductor.

$$i=\frac{6.19\times10^{-23}n_i(\mu_p+\mu_n)(N_A)^{1/2}(V_{DT}-V)^{1/2}\left(\exp^{\frac{V}{2T}(1.16\times10^4)}-1\right)}{1-\exp\left(\frac{-(V_{DT}-V)}{2T}(1.16\times10^4)\right)} \quad (4)$$

The nonequilibrium theory for the forward characteristics predicts a current density given by equation 5 at low voltages (to ~0.1 volt), one which depends on the same factors at somewhat higher voltages with the value of the exponent changing to $(1/2)(V/kT)$.

$$i=2.37\times10^{-27}n_i^2T^{1/2}\left[\frac{\mu_p^{1/2}\mu_n}{\tau_p^{1/2}}\rho_n+\frac{\mu_n^{1/2}\mu_p}{\tau_n^{1/2}}\rho_p\right]\left(\exp^{\frac{V}{T}(1.16\times10^4)}-1\right) \quad (5)$$

At high forward voltages, the current increases directly with the voltage with the slope depending upon the conductance of the bulk material as modulated by carrier injection. The general forward characteristic depends upon consideration of both field and diffusion currents and has not been worked out.

The question of the mechanism of the breakdown of silicon *p-n* junctions has not been completely resolved although the avalanche mechanism seems probable. Recent empirical results have related breakdown voltages (V_b) to resistivities as given in equations 6.

$$V_{b_n}=86\rho_p^{0.64}$$
$$V_{b_p}=23\rho_p^{0.75} \quad (6)$$

In the process of fusing the counterelectrode, a recrystallized, usually highly doped, region of material of opposite conductivity type to that of the starting blank is produced. Thus, the properties of the recrystallized layers usually drop from the equations.

With values of parameters (which may be assumed uniform in the material used for making silicon rectifiers) given in the literature, $E_G=1.21eV$, $\mu_p=490$ cm² per volt-second, $\mu_n=1{,}100$ cm² per volt-second, the theories predict rectification with any values of lifetime or resistivities. Dice of silicon with fairly uniform resistivities can be obtained. Furthermore, in the range of 10 ohm-cm the resistivities do not change appreciably in the processing to be described so that measurements of resistivities before fusion are meaningful. Very-high-resistivity material may change its resistivity, or even type, on heating. Prediction of its behavior depends on a detailed knowledge of the crystal impurities and defects.

Unfortunately, the lifetime across the surface (y z plane in Fig. 1) of a *p-n* junction cannot be measured. This lifetime may be expected to vary in fused

junctions for two principal reasons: (1) defects in the original crystal blank; (2) internal unwet areas. The surfaces of internal unwet areas should be coated with thin films of the electrode solders so that the lifetimes at the peripheries of these regions may be expected to be very low. If the recrystallized region is sufficiently imperfect or of very small extention, as occurs, for example, when recrystallization is not carried out correctly, the properties of the recrystallized layer may no longer be neglected. In such cases, the complete equations must be used. It is seen from equation 2 that the total current will be increased as the lifetime in the recrystallized layer is decreased. If the recrystallized layer thickness (x) is less than the diffusion length (L), the diffusion current in the recrystallized region is increased by the factor L/x.

An equally serious problem in measuring lifetimes in fused junctions in that associated with determining the lifetime in the regions of the exposed edges of the p-n junctions. An additional problem arises in relating surface and bulk lifetimes after fusion to the bulk lifetime measured before fusion and processing parameters. In the usual process, the bulk lifetime of silicon decreases considerably.

Thus, some success has been achieved in relating breakdowns to resistivities since reliable resistivities can be measured and sufficiently perfect junctions made to maintain surface leakage currents small enough as to not interfere with estimation of the breakdown point. On the other hand, it has proved to be more difficult to relate theoretical and experimental currents since exact knowledge of bulk and surface lifetimes in the finished junction is required. The characteristics of finished junctions and rectifiers are discussed in the section on cell and rectifier properties. For the moment, the problem is the intelligent selection of silicon cell components to give useful rectifiers.

Basic Cell Fabrication

Choice of Cell Components

Any rectifier cell consists of the parts shown in Fig. 1. The parts in the figure are discussed in order of their importance to the finished device; i.e., (1) silicon, (2) counterelectrode solder, (3) base solder, (4) counterelectrode, and (5) base electrode.

1. *Silicon*

The resistivity of silicon for very-small-area junctions may be selected to give breakdowns distributing near the predicted values, i.e., for 100-volt breakdown about 2- or 3-ohm-cm material is required. In larger areas cells, breakdowns are not as sharp and the resistivity must be selected on the basis of empirical results to give the average value of the distribution of "breakdowns" desired. With n-type silicon about 10-ohm-cm material and with p-type silicon 30 ohm-cm is suitable for the manufacture of cells with breakdowns distributing over 50 volts to 300 or 400 volts.

Silicon crystals used were grown from du Pont silicon in both needle and compact forms. Crystals were grown in vertical pulling furnaces with quartz crucibles in graphite holders. Slow rotation was employed in pulling. A carefully cleaned inert gas of helium was employed when doping silicon n-type with arsenic. Crystals doped n-type with gold and silver have been grown in vacuum. P-type crystals have been grown in vacuum without any added doping agent, residual boron contributing the acceptor levels.

Average lifetime in ingots of silicon of about 20 μsec is suitable for the production of silicon rectifiers under discussion. Average lifetime in the finished junction is in the range 1 to 5 μsec.

Crystals with grain boundaries or excessive lineage do not give results as good as those from perfect single crystals. In production, it is difficult to detect any bad effect of twinning, however.

No effects of electrical anisotropy have been considered in the theoretical results and none have been observed experimentally. Crystals grown in the (111) and (100) directions have been used with equal success. There are probably small differences in properties which were not detected with the random error residual present.

The listing of some of the mechanical properties of silicon is essential to the later discussion of counterelectrodes, counterelectrode solders, base solders, and bases. The silicon must be sufficiently strong to withstand mechanical stresses occurring in manufacture and application. The applications will include military ones so that, for general use, the silicon must be capable of withstanding several conditions of shock, mechanical vibration, temperature variation, etc., imposed by military specifications, for example, *MIL-E-5272-A*.

The thermal expansion coefficient was measured in the (111) direction and perpendicular thereto in the range of temperatures from −60 C to 800 C. Samples were of sizes 1/4 by 1/4 by 2 inches and 1/4 by 1/4 by 1 inch. The thermal coefficients of expansion in the (111) direc-

Table II. Binary Counterelectrode Alloys

Alloy	Solidus of Binary System	Notes
Al-Ag	~558	Addition of Ag to Al may lower solidus, but the effect is small
Al-Cu	~510 (of ternary)	Addition of 3–4% Cu may lower solidus to range approximated, but result is little improvement beyond pure Al
Al-Mg	~451	Addition of Mg to Al lowers the solidus. The modulus will change little
Al-Ga	~425	Addition of Ga lowers solidus to the indicated range. The modulus will decrease. The resulting alloy is very ductile
Ag-Al	~780	Addition of Al to about 5% will lower solidus considerably and may provide *p*-type conductivity
Ag-In	~693	Additions of In to about 20% will lower the solidus considerably. The modulus may be expected to decrease
Ag-Ga	~724	Addition of Ga to 12% will lower the solidus and the modulus
Cu-Al	~1020	Al bronzes will not appreciably reduce solidus temperatures
Cu-Ga	~909	Solidus should be reduced as well as the bulk modulus of the ternary
Cu-In	~715	Solidus will be reduced considerably. The effect on the modulus is unknown
Au-Al	~417	Addition of Al can lower the solidus to the range indicated. The Au-Al alloys are extremely brittle and cannot be rolled
Au-In Au-Ga	?	Small amounts of In and Ga dissolve in Au, but phase diagrams are not available. The resulting alloys with Ga dope silicon *p*-type as desired. The low modulus of Au and its ductility are not adversely affected

tion were 4.23, 4.16, and 4.26, by 10^{-6} inch per inch C in three trials above room temperature; in the perpendicular direction 3.66, 3.58, 3.85, by 10^{-6} inch per inch C in three trials. Averaged below room temperature to −60 C, the coefficients were approximately 2.0 by 10^{-6} inch per inch C in both directions.

The modulus of elasticity and ultimate stress in silicon were measured. With the small specimens used, a variety of results for ultimate stress were obtained from 12,650 to 21,550 psi (pounds per square inch). The variation resulted from the irregularities in shape of specimens that occurred during cutting, lapping, and etching. Values of Young modulus were more consistent and varied from 22.6 to 32.5 × 10^6 psi. The ultimate elongation is seen to be very small, approximating 0.7 mil per inch. Consequently, the mechanical stresses must be small to prevent cracking of the silicon during preparation or operation. Moreover, the electrical properties and dependence of these on temperature cycling are related to the strain in the silicon lattice.

Besides having appropriate electrical and mechanical properties, the silicon semiconductor must be stable under conditions of long operation of the rectifier. Diffusion coefficients of impurities in silicon are small so that at temperatures of 200 C the rates of diffusion of donor and acceptor impurities are low. Thus, bulk diffusion does not seem to be important in the alteration of the silicon properties with period of operation of rectifiers, as is true in the selenium rectifier.

The thickness of the wafer of silicon used depends upon the penetrations of counterelectrode and base solders in the fusion operation. In well-prepared rectifiers, the thickness of these solders is dictated by mechanical factors discussed later so that the desired thickness of silicon can be calculated from consideration of the diffusion length of injected carriers in the finished rectifier cells. However, practical factors of control of the fusion operation place a lower limit on thickness for optimum yields of good cells. This thickness is in the range of 8–10 mils for the silicon in the process under discussion.

The silicon surface must be carefully lapped and etched after slicing in order to present a clean, uniform surface to the counterelectrode alloy. Successful rectifier cells can be made with blanks etched to a smooth specular surface or to a satin finish. The latter surface results when very little material is removed after lapping.

2. *Counterelectrode Alloy*

In the fused silicon rectifier, the *p-n* junction is produced by melting an appropriate alloy in contact with the prepared silicon blank. On cooling, silicon, dissolved in the alloy, redeposits on the base silicon forming a layer of opposite conductivity type to that of the bulk and producing the *p-n* junction. The exact choice of alloy dictates the fusion temperature. However, in all cases, the recrystallization must be carried out in such a manner that the temperature decreases from the alloy to the silicon in order to obtain the necessary thickness of redeposited silicon, free of metal inclusions and defects, of reasonable lifetimes. It has been found possible to use rapid cooling rates of approximately 50–100 C per minute in the range of redeposition, provided the correct temperature gradient is employed.

The counterelectrode alloy, besides producing a silicon layer of the desired conductivity type, must fulfill a number of other conditions:

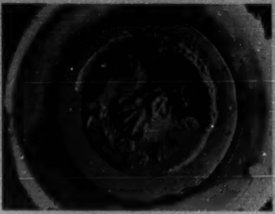

Fig. 2. Cracked silicon cell

(*a*). It must be liquid at a temperature as far as possible below the melting temperature of silicon or the other components of the cell.

(*b*). It must wet the silicon and counterelectrode.

(*c*). It should be solid at all temperatures encountered during processing after the fusion cycle and solid, mechanically, and chemically stable during storage or operation (for safety 400 to 500 C).

(*d*). It should have a low vapor pressure at all temperatures encountered in the fusion cycle.

(*e*). It should not contain diffusible traps.

(*f*). It should have high thermal conductivity.

(*g*). It should not produce excessive strain in the silicon.

Table III. Binary Alloys for Counterelectrode Solders on P-Type Material or Base Solders on N-Type Material

Alloy	Remarks
Au-Sb	Small amounts, 0.01 to 0.1% (per cent), of Sb in Au produce an alloy which retains the properties of pure Au and which dopes silicon n^+. Larger amounts of Sb produce more brittle alloys which are difficult to roll and which crack upon temperature cycling
Au-As	The alloy is similar to the Sb alloy. As is somewhat less convenient to work with
Cu-Sb	Additions of Sb up to about 5 wt (weight) % will dissolve in Cu and lower the solidus to about 900 C. The solidus of the ternary with silicon may be expected to be lower, but not sufficiently so as to make the alloy interesting
Cu-As	Additions of As to about 7 or 8 wt % will dissolve in Cu. The solidus is lowered to 689 degrees but the liquidus remains quite high (980 to 990 C). The silicon ternary will also have a high liquidus
Ag-Sb	Additions of Sb to about 7 wt % will dissolve in Ag and lower the solidus to about 780 C, the liquidus to about 900 C. The Ag-Sb alloys are less brittle than the corresponding Au-Sb alloys
Ag-As	Additions of $4\frac{1}{2}$ wt % As will lower the solidus to 595 C, the liquidus to about 880 C. The ternary with silicon should have a still lower solidus and liquidus temperature

Table IV. Alloys of Ag with Lower Solidus Temperatures than Pure Ag

Alloy	Solidus Temperature, C	Element Added
Ag-Cd	730	36.5 wt % Cd
Ag-Cu	779	8.8 wt % Cu
Ag-Ge	640	4.5 wt % Ge
Ag-Pb	304	about 4% Pb
Ag-Sn	724	13.3 wt % Sn
Ag-Zn	710	22 wt % Zn

The first condition arises from the desire to retain the original lifetime characteristics as much as possible. It is not absolutely necessary that the counterelectrode solder remain solid during processing and good cells have been made by a process in which the condition was violated, but a solid electrode simplifies process controls. The fourth condition is desirable from the standpoint of the ease of post-etching and again is not essential. Condition *e* expresses the desire to retain lifetimes during processing steps which take place at high temperatures where diffusion is rapid. The temperature drop in the solders should be low to permit the greatest possible heat dissipation within the cell, as discussed in the section on encapsulation and heat dissipation. The electrical properties depend upon strain to some extent, but more important, the silicon must be safely below its ultimate elongation in the range of temperatures found in the processing of the basic diode and application of finished rectifiers.

Condition *g* can be re-expressed in terms of the properties of the counterelectrode solder and silicon by observing that the strain in the silicon (part *1* in Fig. 1) is given by the following, see Appendix II:

$$\frac{S_3}{E_3}=\left\{\frac{\sum_{n=3\text{-}5}(\alpha_n-\alpha_3)t_nE_n(T-T_4)+\sum_{n=1,2}(\alpha_n-\alpha_3)t_nE_n(T-T_2)}{\sum_{n=1\text{-}5}E_nt_n}+\frac{(T_2-T_4)\sum_{n=1,2}E_nt_n\sum_{n=3\text{-}5}E_nt_n(\alpha_n-\alpha_3)}{\sum_{n=1\text{-}5}E_nt_n\sum_{n=1\text{-}5}E_nt_n}\right\} \tag{7}$$

where

S = stress in the silicon
E_n = modulus of elasticity of element n
α_n = coefficient of thermal expansion of element n
T_4, T_2 = solidus temperatures of base and counterelectrode solders
t_n = thickness of element n

It is noted that the minimum stress in silicon is obtained with a low solidus temperature for the counterelectrode alloy, a low-bulk modulus, a small thickness of the alloy, and a coefficient of thermal expansion matching that of silicon. Thus, condition *f* is restated

(*h*). The product of thickness, modulus of elasticity, and difference of thermal coefficients of silicon and the alloy must be as small as possible.

(*i*). The solidus temperature of the alloy should be as low as possible consistent with condition *c*.

The eight conditions should be considered before noting the doping effect of the alloy since the addition of trace elements may adequately dope the redeposited silicon layer without affecting the listed properties of the alloy. The first four conditions limit the useable pure elements to silver (Ag), gold (Au), aluminum (Al), and copper (Cu). Antimony (Sb) and magnesium (Mg) have the correct melting ranges and are expected to wet the silicon and counterelectrode, but both should form very brittle alloys with silicon. In addition, the vapor pressure of Sb is too high for use in vacuum fusion. The discussed properties of the useful pure metals are listed in Table I. The metals noted all have good thermal conductivities, Al having the poorest. Of the four alloys, Cu seems least attractive, having the highest product of bulk modulus and difference of expansion coefficients and a high solidus. The solidus temperatures of Ag and Cu are too high, that of Al somewhat higher than the set range to 500 C. The solidus of the Au-silicon alloy is somewhat lower than desired, but the other properties are so attractive that the discussion will retain Au and its alloys.

To produce the correct *p*-type of redeposited silicon (against *n*-type bulk silicon), acceptors must be present in alloys of Cu, Ag, and Au. Thus, the binaries of these elements with gallium (Ga), indium (In), or Al should be considered. To produce the desirable heavily doped *n*-region in contact with *p*-type bulk silicon, donor elements must be added: phosphorus (P), arsenic (As), Sb. Of these, Sb is the least difficult to handle and is less volatile in the fusion cycle. Thus, binaries of Sb and Ag, Cu or Au are interesting.

To summarize, it is desirable to reduce the solidus of Ag-silicon, Cu-silicon, and Al-silicon alloys and the modulus of elasticity by addition of another element or elements. It is also necessary to add an acceptor element to Ag and Cu alloys for use as counterelectrode solders against *n*-type silicon, and to add a donor element Sb to the same alloys for use as counterelectrode solders aganst *p*-type silicon.

Table V. Ternaries of Ag, Pb, Sb

Ternary	Liquidus, C	Solidus, C	Ductility
Ag—1% Sb—1.5% Pb	910	555	soft
Ag—1% Sb—2 % Pb	~907	525	soft
Ag—1% Sb—3 % Pb	904	490	soft
Ag—1% Sb—4 % Pb	~890		soft
Ag—1% Sb—5 % Pb		415	soft

Table II lists possible binaries for use as counterelectrode solders against *n*-type silicon. Reviewing the tabulated items, it appears that additions of Ga and Mg may noticeably reduce the solidus temperature of an Al counterelectrode solder. The modulus of a Mg-Al system will change little whereas that of the Ga-Al system will be reduced. The Ga-Al alloys are very ductile.

It appears that the addition of Al to Cu and Ag will not produce electrodes superior to those of pure Al. Although the solidus temperature of Au is reduced markedly with small amounts of Al, the resulting intermetallics formed produce a very brittle alloy which cannot be rolled. Alloys of Ga with Ag and Cu have not been investigated by the author. These may be expected to have lower solidus temperature and bulk moduli than those of the pure metal-silicon alloy, but it is doubtful that the properties will be superior to those of Al-silicon or Al-Ga-silicon alloys. The Au-Ga system dopes silicon *p*-type and has all the desirable properties of the Au counterelectrode alloy.

In order to control electrode penetration, Al-silicon eutectic alloy has been employed instead of the Al element.

Al or Al-silicon eutectic alloy has been used as counterelectrode material in almost all of the experiments with *n*-type bulk silicon. Al-Ga alloys have been studied as a possible improvement over these. However, the Al and Al-silicon counterelectrode materials have proved to be satisfactory and capable of producing rectifiers in which excessive strains do not occur during temperature cycling from −55 to 200 C. In the development of small communication diodes (by the fused-wire technique), Au-Ga alloys have been employed. However, a new type of small-area diode has been developed which is more promising than the fused-wire type. The new diode employs the same counterelectrode solders as the large power types.

The counterelectrode solder thickness is approximately 2 mils, this being sufficiently small to prevent excessive strain

Table VI. Properties of Counterelectrode Materials

Material	Elastic Modulus, Psi $\times 10^6$	Coefficient of Thermal Expansion, Inch Per Inch C $\times 10^{-6}$	Thermal Conductivity, Calories Per Second (Cm^2) (C Per Cm)
Mo	50	5–6*	0.35
Mo, Kovar-alloy-clad	50	5–6*	0.35
Mo, Ni-clad	50	5–6*	0.35
Kovar alloy	19.5	4 to 445 C >5 at high temperature	0.03
Zi	11	5	0.04
W	50	4.3	0.48
Ta	27	6.5	0.13
Invar alloy (36% Ni, Fe)	21	2.7 to 200 C 11.5 to 200–315 C 15.5 to 315–425 C	0.025
Hypernik alloy (47–50% Ni, Fe)	24	5.5 in small range	0.029
Cr	36	6.2	0.16

*See Table VII.

Table VII. Average Coefficient of Thermal Expansion of Mo Sheets (Inch Per Inch C $\times 10^{-6}$)

Temperature Range, C	Plain Mo Sheet	Mo Sheet, Kovar-Clad One Side	Mo Sheet, Kovar-Clad Two Sides	Mo Sheet, Ni-Clad One Side and Stainless-Steel-Clad One Side
100–200	5.18	5.60	5.00	5.58
100–300	5.27	5.63	5.28	5.67
100–400	5.43	5.67	5.37	5.73
100–500	5.55	5.74	5.75	5.75
100–600	5.63	5.83	5.87	5.77
100–700	5.69	5.93	5.95	5.77
100–800	5.73	5.99	6.01	5.78
100–900	5.75	6.04	6.06	5.78

Table VIII. Parts Employed in Communication Diode and Larger Rectifier Sides

	N-Type Communication Diode	N-Type Silicon Power Rectifier	P-Type Silicon Power Rectifier
Counterelectrode	Ta	Mo, Ni-plated one side	Mo, Ni-plated one side
Counterelectrode solder	Al-silicon eutectic	Al-silicon eutectic	Au-1% Sb
Silicon	Chosen on basis of breakdown desired by formula	~10 ohm-cm	±30 ohm-cm
Base solder	Ag-Pb-Sb	Ag-Pb-Sb	Al-silicon eutectic
Base electrode	Mo, Ni-plated or Ta	Mo, Ni-plated	Mo, Ni-plated

and thick enough to ensure uniform wetting of parts which have dimensional tolerances. The solder is carefully cleaned before use.

The counterelectode solders for use with *p*-type silicon have the same requirements as the base electrode solders for use with *n*-type silicon except that traps may be present in the base solders provided they will not diffuse into the bulk silicon and lower the diffusion length below the counterelectrode-base extension.

3. *Base Solder*

The base solder to *n*-type material should have all the desirable mechanical properties noted in the discussion of the counterelectrode solder and should in addition produce an n^+ region in the silicon near the contact. Again, the same base materials of Au, Cu, and Ag are possible. Al is quite soluble in silicon and diffuses faster in silicon than the group V elements so that doping of Al with these elements will not produce *n*-type recrystallized silicon regions.

It is desirable in considering base contacts and necessary in producing a counter-electrode alloy to *p*-type material to dope the metals Au, Cu, and Ag with group V elements. In a vacuum fusion process, it is convenient to use Sb as the element. However, As has been employed with similar results. The alloys of Au, Cu and Ag with Sb and As are discussed in Table III.

The Au-Sb alloys are brittle, but make possible base or counterelectrode solders provided the processing temperatures do not exceed 350 C. The Cu alloys appear to have higher solidus and liquidus temperatures than the corresponding Ag alloys with no particular advantages. The Ag-Sb and As alloys become more difficult to roll and brittle as the Sb and As contents are increased. On the other hand, the solidus temperatures are not reduced appreciably by traces of the elements. The Sb alloy is preferred over the As one for vacuum fusion operations.

An alloy of Ag-5 wt % Sb was first employed as base solder in the development work. However, an appreciable number of cells cracked during processing and in operation as a result of thermal stresses in the silicon. Fig. 2 shows the appearance of a cell that has been destroyed by excessive thermal stresses. A very sensitive method of detecting stress in silicon cells is the measurement of forward drops at high currents as a function of number of temperature cycles (−55 C to 200 C) to which the cells have been subjected. If stresses are excessive, a gradual increase in forward drop will result. Reverse characteristics will behave in an erratic manner.

The high percentage, 5 by weight, of Sb in the Ag alloy need not be retained for doping considerations. However, another metal must be added to reduce the solidus temperature and the modulus of elasticity and increase ductility. Table IV lists some possibilities. Some of these cannot be used in a vacuum system. The most attractive are the alloys of Ag with germanium (Ge) or lead (Pb). Both alloys have been employed with success. However, the solidus and modulus of the Ag-Ge alloys are higher than in the corresponding Pb alloys. Hence, the Pb alloys are preferred for producing relatively strainfree silicon cells. Interesting ternaries of Ag, Pb, and Sb are listed in Table V. The solidus temperature can be tailored to the desired range.

The Ag-Pb-Sb solders have been employed as base solders on *n*-type materials. Cells made with such alloys are absolutely free of cracks as observed under microscopic examination. Hundreds of cells have been studied without observing failures.

The Au-Sb alloys have been employed as counterelectrode solders on *p*-type material. Al, Al-silicon eutectic, or the same with addition of Ga produce excellent base contacts to *p*-type bulk silicon.

The base solder thicknesses are again held to two or three mils. The range is such that uniform wetting can be obtained with the parts and jig tolerances permitted and excessive strain from the base electrode is avoided. Base solders are carefully cleaned before use.

4. *Counterelectrode*

The counterelectrode material must satisfy several requirements:

(*a*). It should have close to the same thermal expansion coefficient as the silicon over the entire range of temperatures encountered during operation and processing.

(*b*). It should have a bulk modulus high if the coefficient in (*a*) matches well and low if it does not.

(*c*). It should have high thermal conductivity.

(*d*). It should have fabrication possibilities and be reasonable in cost.

(*e*). It should be, if possible, inert to the action of etches employed in processing the basic diode.

(*f*). It should not contaminate the redeposited silicon.

(*g*). It should be wet by the counterelectrode solder in the range of fusion temperatures employed.

(*h*). It should be wet by solders used in attaching external leads.

Table VI lists the properties of a number of interesting materials, while Table VII gives values of thermal expansion coefficients measured on molybdenum (Mo) sheet, plain and clad, with a mil or so of metals. There appears to be no significant differences in expansion coefficients. The values averaged from 0 to −60 C were 5.2, 5.62, and 5.48 × 10^{-6} inch per inch C for plain Mo sheet, Mo sheet clad with Kovar alloy, and Mo clad with nickel (Ni) and stainless steel.

Chromium (Cr) cannot be obtained commercially in sheet form and should not be considered. While zirconium (Zi) has some interesting properties, the material is in short, government-controlled supply.

The iron (Fe)-Ni alloys do not match the coefficient of expansion of silicon over a sufficiently large range to be considered. Provided the counterelectrode and base solders do not freeze below the inflection point in the thermal coefficient of expansion, Kovar alloy may be used without cracking the silicon. It can be soldered with soft solders. However, the thermal conductivity is so low that it should not be considered a suitable electrode material except in applications of low power dissipation.

Of the elemental metals, tungsten (W) best matches silicon in coefficient of thermal expansion and has the highest thermal conductivity. The material is difficult to fabricate and relatively expensive. For very large silicon rectifiers, it appears to be the ideal base.

Tantalum (Ta) can be easily fabricated but is also expensive. It has a peculiar advantage in that it is relatively inert to the action of etches employed in the processing of cells. Thus, cells made with electrodes of Ta can be etched in batches without masking. The element can be welded, but cannot be wet by soft solders in encapsulation steps. It may be clad or plated with noble metals to permit soft soldering.

Mo can be easily fabricated and is less expensive than W or Ta. It is attacked by etches and must be protected in some manner. It is easily welded or soldered to with soft solders when clad with Kovar alloy, or plated with Ni or noble metals, tinned with Ag, tin (Sn), and indium (In). When the material is used as counterelectrode material, the surface next to the counterelectrode solder is not clad or plated.

5. *Bases*

The base electrodes are chosen on similar considerations to those previously discussed. Base electrodes may be clad, plated, or tinned on both sides without damage to the cell properties.

In practice, a variety of electrode materials have been employed, Ag-tinned Mo, Ni-plated Mo, Kovar- and Ni-clad Mo, Ta, platinum (Pt)-clad Ta, and W. For small diodes in which the component part expense has not been great, Ta has been employed because of its ease of fabrication and resistance to etch chemicals. In larger diodes, Ni-plated Mo has been found to be most economical and quite satisfactory.

FUSION OF CELL COMPONENTS

The parts as discussed under "Choice of Cell Components" are assembled in graphite jigs. In cases of the communication diode and larger power rectifier cells, the parts given in Table VIII are employed. Thickness and preparation are as described previously. Areas are chosen to handle the current desired.

The graphite jigs are heated rapidly in vacuum by radio-frequency coils to the fusion temperatures which approximate 900 C for the *n*-type and 800 C for the *p*-type cells. The jigs are then cooled rapidly to 500 C and more slowly to room temperature.

The base electrodes of the communication diode and the both electrodes of the power rectifier cells are masked, the former with Apiezon wax, the latter with Pb-Sn solder prior to etching. Etching takes place in a mixed acid etch. Careful washing, rinsing, and drying steps precede the encapsulation. Examples of finished rectifier cells are shown in Fig. 3.

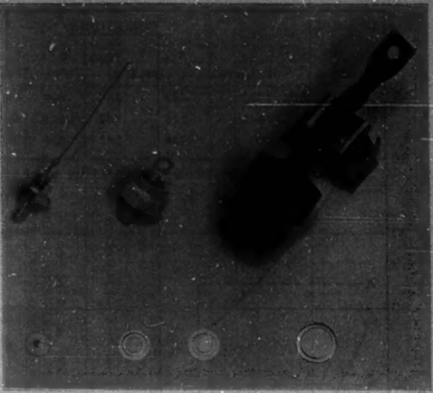

Fig. 3. Rectifier cells and encapsulation

Encapsulation and Heat Dissipation

The silicon rectifier cell must be protected from water vapor in order to obtain the optimum performance of the unit. The sensitivity to moisture is most pronounced in those units which most closely approach the nonequilibrium theory (small communication diodes) since in such units the external surface lifetimes are relatively high compared with those of poorer units and are more easily degraded. In addition, external connections must be made to the cell which will not introduce stresses in the silicon when the cell is subjected to all the environmental conditions imposed by industrial and military applications. Consequently, all silicon rectifiers are hermetically sealed in suitable capsules.

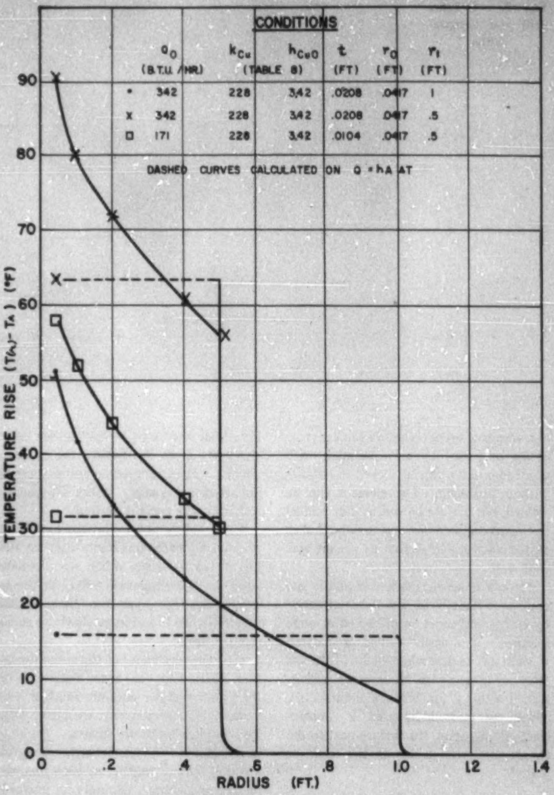

Fig. 4. Temperature drop in cooling fins by equation 8

In addition to supporting the external leads and giving humidity protection, the cases must provide for the dissipation of heat to a heat sink. In almost all applications, air cooling is desirable so that the heat sink is either the ambient atmosphere or a metal member to which the unit may be fastened in some manner. The latter must then dissipate the heat to the atmosphere. In this section, the general problem of dissipation of heat from the cells to the atmosphere will be considered although the rectifier units are available without fins, but with means of making connection to such.

Humidity Protection

In the course of development, various methods of protecting the cell against water vapor were used including, for example, coating with silicone rubbers and encasing in oxide power slurries, but all have been abandoned for general use in favor of hermetic sealing in gas. In selected applications, sealing in solid insulators may be of interest.

All cells are subjected to humidity and temperature cycling tests so that the requirements on glass or ceramic seals employed in the encapsulation are demanding. The case and seal assemblies are carefully cleaned and baked out in vacuum prior to use.

External Lead Connection

Because of the low ultimate strain of silicon, external lead connections must be made with considerable care. In order that free expansion might be retained in the x direction of Fig. 1, a flexible lead is connected to one electrode; in the cases under consideration, it is connected to the counterelectrode. In larger rectifier units, it is desirable to dissipate heat through both electrodes, consequently, a problem arises of making flexible parts of sufficiently low thermal resistance to permit significant heat dissipation. In smaller units, the problem reduces to one of making flexible contact with leads of sufficient cross section to handle the electric currents. A variety of flexible leads have been designed and used. In one case, a flexible lead was required which would permit the rectifier unit to operate in as small a space as possible under high centrifugal forces on the shaft of a generator. The flexible member required symmetry so that under starting and stopping conditions, the cell would not be subjected to dangerous forces. This member took the form of a flat notched hollow convex lens. In other cases, S-shaped members have been employed. There is a distinct advantage to the use of flat-dish-shaped or corrugated plates or bellows over braided copper wires in that the former may be more easily cleaned of flux employed in soft solder operations. In the soft soldering operations, solders melting safely above the cell operating temperature of 200 C must be used.

In the case of the communication diode shown in Fig. 3, the lead is an integral part of the counterelectrode. Flexible connection to this lead is easily made by welding. In the case of the small diode, requirements of very low leakages dictate extreme cleanliness and absence of flux in all operations.

Connection to the base electrode must be made with care to observe that the additional members, i.e., the solder and case metal, do not contribute to the total stress in the silicon. Equation 7 can be extended qualitatively to the 7-member case, however, symmetry is now lacking and bending certainly results. To dissipate heat adequately, the case base should be many times the thickness of the parts of the basic cell. The thermal coefficients of expansion of materials considered for the case will be high. Consequently, severe strains can result unless the soft solder plastically deforms. It has been found that lead solders are completely satisfactory. Tin may also be used as solder with smaller cells.

The technique employed in the fabrication of the communication diode provides the base of the case in the fusion operation. After this operation the header is welded to the base.

Spreading resistance	0.86	0.134	0.075

CASE DESIGN AND HEAT DISSIPATION

The heat generated in the case must be dissipated by conduction to the contiguous terminals and by radiation and gas or liquid convection to the side wall of the case. Liquid and boiling liquid convection to the case sidewalls have been considered as means of increasing the allowable heat dissipation. However, there are practical difficulties in obtaining sufficiently pure and stable chemicals for use at 200 C. Fluorocarbons are expensive. The long-term stability of silicones may be questioned. In addition, convection liquids tend to clean up the internal case parts and expose the silicon junction to all the resulting contaminants in the liquid.

The radiation from cell to case may be neglected if the case is properly designed since the temperature of the case will approach that of the cell.

The conduction heat losses through one or both of the Mo terminals of the cell can be readily calculated. Table IX lists representative temperature drops within elements of the cell and case. In most common and convenient case designs, the thermal spreading resistance from base of the case to the roots of fins must be calculated. An exact calculation is difficult, but an approximation can be made by averaging the cross-section areas through which the heat flows passing from the bottom of the case to the fins in estimating the thermal resistance. Table IX also lists estimated temperature drops in spreading resistances for typical designs.

The heat at the fins of the case must be dissipated by convection and radiation to the ambient atmosphere. For free convection, combined radiation and convection coefficients of different case materials are estimated to be those in Table X. The usual simple formulas for calculating temperature drops across cooling plates in terms of total areas of plates and heat transfer coefficients are inadequate when considering the case of cylindrical symmetry. An expression for the temperature drop from a finned case to an ambient gas has been developed, Appendix III, which does not neglect the important temperature drop within the fin. The temperature at radius r is given by

$$T(r)-T_A=C_1J_0(qr)+C_2N_0(qr) \qquad (8)$$

where T_A is the ambient temperature $q^2=2h/kt$, h is the combined convection and radiation heat transfer coefficient, k is the thermal conductivity of the fin, t is its thickness, J_0 is the zero-order Bessel function of the first kind, N_0 is the zero-order Bessel function of the second kind. The constants and the temperature at the base of the fin are evaluated in the Appendix III. Fig. 4 shows the temperature drops from silicon to the ambient atmosphere for the conditions given in the figure. Temperature drops with different radius fins are given.

The cases of multiple fins are simply calculated by apportioning the total dissipation among the fins and recalculating the temperature drop. The effect of employing two fins of the same total copper volume as one thick fin is shown in the Fig. 4.

In forced convection, the air-film heat-transfer coefficients may be increased by a factor of ten.

Cell and Rectifier Properties

PROPERTIES OF THE BASIC CELLS

Small-Area Rectifier Cells

The breakdown voltage of small-area rectifiers (Fig. 3, junction area 0.0020 cm²) shows some agreement with predicted values given previously. As noted, the breakdown voltage, depending on resistivities alone (which can be measured and are reasonably uniform), corresponds reasonably well with predicted values. Fig. 5 shows the reverse characteristics for a good small-area rectifier cell. With known values of physical constants and properties of the silicon semiconductor assumed in Table XI, the reverse current of the rectifier is calculated by equation 2 to be 1.8×10^{-10} amperes per cm².

The field-controlled current by equation 1 is 2×10^{-1} amperes per cm² at 100 volts. All the calculated currents are shown in the figure. It is apparent that the use of the averaged lifetime in the table is not adequate to explain the actual currents observed. On the other hand, the field-controlled current is in excess of that actually measured so that currents must be diffusion controlled. A unique combination of the two currents or the addition of diffusion-controlled currents with different lifetimes is not possible with the experimental evidence and data on hand.

Table X. Conduction, Combined Radiation and Convection Coefficients

Material	Btu Per Hr Ft² Deg F	Material	Btu Per Hr (Ft²) (Deg F Per Ft)
h_{CuO}	3.42	k_{Cu}	228
h_{Cu}	1.52	k_{Al}	89.6
h_{Al}	1.38		

Table XI. Values of Si Parameters Employed in Calculations

$E_g=1.21$ electron volts
$T=298$ K
$\mu_n=5.5\times10^6T^{-1.5}\sim 1{,}100$ cm² per volt-second
$\mu_p=2.4\times10^8T^{-2.3}\sim 490$ cm² per volt-second
t (semiconductor thickness) $=1.27\times10^{-2}$ cm
$p_p\sim10^{18}$ per cm³
$\tau_p=3\mu$ sec
$\rho_n=20$ ohm-cm
$A=1.5\times10^{33}$ cm⁶/°K³
V_D (intrinsic to 20 ohm-cm) $=0.321$ electron volts

The forward currents at low voltages are compared with values calculated from equations 4 and 5, with modification of the exponent to $(V/2kT)$, in Fig. 6. The agreement between theory and experiment is quite good provided the reverse saturation current observed experimentally is employed in the calculations. This means that the term exp $(V/2kT)$ is essentially correct in the range of voltage of 0.5–0.6 volts although the diffusion length, or lifetime, is not adequately evaluated. The asymptotic value of the slope of the characteristic is compared with the value calculated on the basis of the quasi-equilibrium junction. On the basis of the nonequilibrium junction with linear dependence of injection carrier density on the distance across the rectifier cell, and density calculated for the given lifetime of 3 μsec, the conductance is extremely high. The carrier density at the *p-n* junction is perhaps 10^{20} per cm³. With either approximation to the conductance, the average conductivity of the bulk region is in the range of $n(\mu_n+\mu_p)\ q\sim10^{20}\ (1.6\times10^{-19})\ (\mu_n+\mu_p)=16\ (\mu_n+\mu_p)$. In this range of carrier densities, the mobilities in Table XI are much too high, consequently the conductance cannot be calculated.

The reverse characteristic has the temperature dependence shown in Fig. 7. Again, the temperature dependences of field- and diffusion-controlled currents are calculated and compared with the experimental values.

Large-Area Rectifier Cells

Data, analogous to those given for the small-area cell, are given in Figs. 8–10 for a cell of junction area 0.3 cm².

In the reverse direction, it is observed

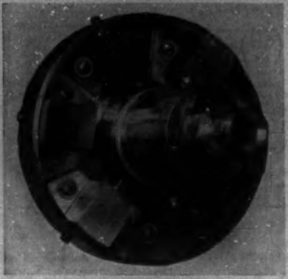

Fig. 11. Rotating rectifier assembly

that the current does not show a saturation value. The field-controlled current, on the other hand, is much larger than actually observed. Consequently, the lifetime is considered to vary across the junction, particularly at or near the surface edges. A unique description of the current is not possible with the data on hand.

The forward characteristic agrees much better with the values predicted by theory. The conductance of the carrier-modulated bulk is lower than calculated, which indicates room for improvement in the forward drop.

The temperature dependence of the leakage of cells shown in the figure is representative of that of many production cells. It should be noted that the current increases less with temperature at high voltages than at low voltages. In many cases at sufficiently high voltage, the leakage currents decrease with temperature. If an effective lifetime for the junction is calculated such that the theoretical reverse current at high temperature (which current is reasonably constant with voltage) matches that observed experimentally, an exponential dependence of lifetime on temperature results on matching the theoretical saturation current with the experimental at an arbitrary low voltage, say 1 volt. It is apparent that the power rectifier cells presented in this paper cannot be adequately described in terms of lifetime parameters.

PROPERTIES OF RECTIFIERS

Complete rectifiers have been tested under all the environmental conditions required under the *MIL-E-5272-A* specification. Such tests have included humidity, salt-spray, vibration, and temperature-cycling tests. With good encapsulation and solution of cracked header problems, no difficulty was expected or experienced in salt-spray and humidity tests.

Temperature-cycling tests were carefully conducted to detect any increase in forward drops indicative of cracking silicon. With the solders described in the previous section, success has been achieved in eliminating cracking as an important problem in the silicon rectifier.

Ageing tests have been in progress for over 15,000 hours. The characteristics of the cells have been stable.

Rectifier units have been mounted in various assemblies to test the performance under different load conditions in free and forced air convection. The rectifier stack shown in Fig. 11 was designed to rectify the exciter current in a brushless aircraft generator. In such an application, the rectifiers were cooled by oil at 150 C flowing through the shaft of the generator. The generator was subjected to overspeed tests to 13,000 rpm so that the cells were required to withstand centrifugal forces of 10,000 g.

The single-phase assembly in Fig. 12 was designed for industrial applications requiring about 30–40-ampere d-c output at voltages to 200 volts in free air convection.

A high-power application required the use of the base cell in Fig. 3. This single rectifier cell, properly mounted, is capable of handling currents as high as 1,000 amperes on short-circuit condition for about 5 seconds, and is rated for average current of 150 amperes.

The foregoing illustrate a few of the applications of silicon rectifiers. A number of difficulties have arisen in applying silicon rectifiers. One of the more serious of these is the correct rating of the rectifiers for circuits in which current surges are obtained. Other problems have arisen in the aging of parts of the rectifiers. Such problems, as they have arisen, have been solved by careful process control and rating. It is expected that further difficulties will arise as the silicon rectifier is given wider and wider application. However, the physical and chemical stability of the correctly constructed and carefully encapsulated basic cell are such that the general successful application of the silicon rectifier may be looked for within the next few years.

Appendix I. Quasi-Equilibrium P-N Junction

Assuming an abrupt *p-n* junction of two semiconductors of equal carrier densities, these independent of position, the quasi-equilibrium reverse current can be calculated realizing that the total current across the junction is continuous. Schottky[8] has shown that the current through a metal-semiconductor junction with internal contact difference of potential of V_D is given at reverse voltages over about 0.1 volt by

$$i=\sigma_R\left(\frac{8\pi q n_A^-}{\epsilon}\right)^{1/2}(V_D+V)$$

(electrostatic units)

where, in electrostatic units, i is the current per square centimeter, σ_R is the conductivity at the junction, n_A^- is the density of ionized acceptors in the vicinity of the junction, ϵ is the dielectric constant, V is the applied voltage.

Realizing that the foregoing is the current that flows when V is the drop in voltage in the material on one side of the *p-n* junction, provided σ_R is now the conductivity at the *p-n* junction, V_D is the contact difference of potential intrinsic to material on one side of the junction, the terms can be subscripted one and two for the two sides of the junction and the voltage drops summed to give the following

$$i=\sigma_R\frac{\left(\frac{8\pi q n_A^-}{\epsilon}\right)^{1/2}(V_{DT}+V)^{1/2}}{\sqrt{2}}$$

(electrostatic units)

where V_{DT} is the total of contact potentials V_{D_1} and V_{D_2}. This may be rewritten as in equation 1.

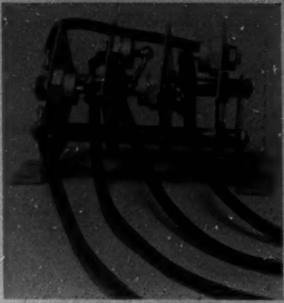

Fig. 12. Medium-power industrial bridge

Appendix II. Stress in a Silicon Junction

In the case of the 5-element sandwich discussed in this paper, a rather symmetrical situation exists. Consequently, a first approximation to the stress in the silicon can be obtained by assuming that bending is absent, and all strain occurs in the plane of the flat elements.

In cylindrical co-ordinates, the radial strain $\delta R/R$ is the same as the strain in the θ_1 direction.

Consider a 5-element sandwich in which elements 3, 4, and 5 are rigidly connected at temperature T_4 by freezing of element 4, elements 1, 2, 3, 4, and 5 are joined by freezing of element 2 at T_2 and stress in element 3 is to be calculated at temperature T. A system of equations:

$$\frac{S_n}{E_n}=\frac{R(T)-R(T_2)[1+\alpha_n(T-T_2)]}{R}\qquad n=1,2$$

$$\frac{S_n}{E_n}=\frac{R(T)-R(T_4)[1+\alpha_n(T-T_4)]}{R}\qquad n=3,4,5$$

$$\sum_n S_n t_n=0\qquad n=1\text{–}5$$

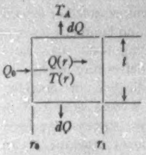
$$\frac{S_n{}^1}{E_n}=\frac{R(T_2)-R(T_4)[1+\alpha_n(T_2-T_4)]}{R}\qquad n=3,4,5$$

$$\sum_n S_n{}^1 t_n=0\qquad n=3,4,5$$

can be solved for the stress S_3 at T in equation 7.

Appendix III. Temperature Drops in Cylindrical Fins

Consider the flow of heat through a cylindrical cooling fin shown in the following cross section:



$$Q(r)=2\pi rkt-\frac{dT(r)}{dr}$$

$$dQ=-h(T(r)-T_A)4\pi r dr$$

Hence

$$\frac{d^2T(r)}{dr^2}+\frac{1}{r}\frac{dT(r)}{dr}+\frac{2h}{kt}(T(r)-T_A)=0$$

or with $T^1=(T(r)-T_A)$, $q^2=\frac{2h}{kt}$,

$$\frac{d^2T^1(r)}{dr^2}+\frac{1}{r}\frac{dT^1(r)}{dr}+q^2T^1=0$$

The solution of this equation is the zero order Bessel function

$$T^1=C_1J_0(qr)+C_2N_0(qr)$$

The boundary conditions, at $r=r_0$,

$$T_0{}^1=(T_0-T_A)$$

$$\left(\frac{dT^1}{dr}\right)_0=\frac{-Q_0}{2\pi ktr_0}$$

allow evaluation of the constants in terms of T_0. Evaluation in terms of Q_0 is possible by realizing that

$$Q_0=-\int dQ=h\int_{r=r_0}^{r=r_1}(T(r)-T_A)4\pi r dr$$

and substituting for $T(r)$ from the equation 8.

Application of Junction Transistors to Carrier-Frequency Computing Amplifiers

W. A. CURTIN
ASSOCIATE MEMBER AIEE

THE PURPOSE of this paper is to describe some of the considerations involved in designing a transistorized summing amplifier which could be used as a building block in a carrier-frequency analogue computer. The basic design philosophy was necessitated by the quality of the transistors commercially available at the start of the development work in mid-1954. Typical transistors are the early type *2N34* and the later type *2N109*.

A need for transistorized summing amplifiers exists in the a-c computers of military fire-control systems where long life, miniature size, and low power consumption are essential requisites. Such a computer may be subjected to extreme environmental conditions, have a limited power source, and may be required to function with little or no maintenance. The transistor, because of its ruggedness small size, and low power requirements, would make a subminiature computer possible. Thus, it appears that the transistor is ideally suited to such an application.

With these thoughts in mind, it is felt that if transistorized components, such as a summing amplifier, could be developed to perform as well as a high-quality vacuum-tube device, then the goals of long life, subminiaturization, and power conservation would be partially realized.

Background

Negative feedback is usually employed to maintain the high accuracies required of a summing amplifier for computer applications. The general form of such an amplifier is shown in Fig. 1. Before proceeding with those considerations peculiar to transistors, it might be well to review briefly part of the theory of the circuit shown in Fig. 1, limiting the discussion to amplifiers having only resistive feedback elements, and the main concern being dynamic accuracy and stability.

For the circuit of Fig. 1, the output voltage is given by

$$E_o=\left[\frac{R_F}{R_{i1}}E_{i1}+\frac{R_F}{R_{i2}}E_{i2}+\ldots\frac{R_F}{R_{ij}}E_{ij}\right]\frac{A\beta}{1+A\beta}\tag{1}$$

where

$A\beta$ = open-loop gain

For reasons of stability, $A\beta$ is necessarily finite; hence the closed-loop gain is not exactly equal to the indicated resist-

ance ratio of equation 1, and therefore gives rise to a static error which may be compensated for by altering the value of either R_i or R_f. It can be shown that a finite amplifier input resistance R_{in}, or input shunting resistance R_b does not affect the closed-loop gain, but only affects the gain stability factor $A\beta$.

More important is the error resulting from variations of $A\beta$ from a design center value caused by transistor (or tube) aging, component tolerances, environmental conditions, and so on. Here the question arises as to how much feedback is required to satisfy a given error specification. The answer to this problem lies in how much $A\beta$ will change with respect to the design center value, $(A\beta)o$. If the maximum expected $A\beta$ variation is expressed as a fraction of $(A\beta)o$, then the value of $(A\beta)o$ required to hold the error to less than a specified amount may be calculated from equation 2

$$(A\beta)o=\left(\frac{1}{e_d}-1\right)\left[\frac{1-(A\beta)n}{(A\beta)n}\right]-1 \qquad (2)$$

where

$(A\beta)n=A\beta/(A\beta)o$
e_d = error

A useful set of design curves is obtained if $(A\beta)o$ is plotted against $(A\beta)n$ with e_d as a parameter. For example, in order to insure a maximum error of 0.1% (per cent), $(A\beta)o$ need only be 110 if $A\beta$ can decrease by 10%, but must be approximately 1,000 if $A\beta$ can decrease by 50%.

From the point of view of stability, a large amount of feedback is troublesome. Alternatively, the problem of stability is significantly reduced if $A\beta$ can be constrained to vary between narrow limits, which, as seen from the preceding, will also permit the realization of a low error. It will be shown later that the inherent limiting phase characteristic of the transistors available for this investigation sets a rather restricted upper limit of stable loop gain which may be realized.

In addition to these notions, all the other well-known virtues of negative feedback apply to a transistor feedback amplifier.[1] Since the design techniques of linear vacuum-tube feedback amplifiers are well known,[2] one's first tendency is to determine whether they might be applicable to an equivalent transistor amplifier. With recognition of the transistor as a new circuit element, a determination should be made of its frequency response, and of the behavior of its gain and terminal impedances, as would normally be done in the designing of the vacuum-tube amplifier.

Gain and Terminal Impedance Variations

It is well known that the intrinsic transistor parameters, which determine the input and output impedances and gain characteristics, vary rather widely between units as a result of the manufacturing process. Within a given unit, variations exist and are attributable to bias conditions and temperature.[3]

For the purposes of the present discussion it is more convenient to consider the variation of the parameters of the low-frequency equivalent circuit rather than that of the intrinsic resistance elements and amplification factors. A convenient form of the low-frequency common-emitter equivalent circuit is shown in Fig. 2 (above), where, if $R_{o\infty} >> R_L$.

R_{io} = short-circuit input resistance $= r_b+(1+\alpha_{cb})r_e$
$R_{o\infty}$ = open-circuit output resistance $= r_c/(1+\alpha_{cb})$
μ_{bc} = reverse open-circuit amplification factor $\approx r_c/\left(r_e+\dfrac{r_c}{1+\alpha_{cb}}\right)$
α_{cb} = short-circuit collector-base current gain $\approx \alpha/1-\alpha$

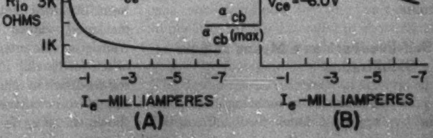

Fig. 3

A—R_{io} versus emitter current
B—α_{cb} versus emitter current

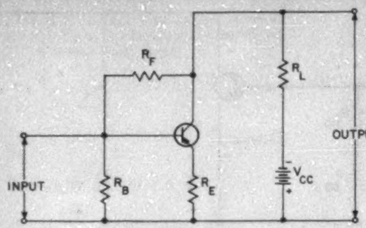

Fig. 4. Common-emitter stage showing self-feedback elements

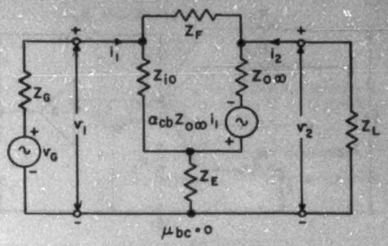

Fig. 5. Common-emitter equivalent circuit for computing the equations of Table I

The common-emitter circuit is used here exclusively, and the discussion restricted to this configuration, since it possesses a voltage phase reversal, and more nearly matched terminal impedances.[4]

Fig. 3 shows the order of magnitude of the variation of the short-circuit input resistance R_{io} and short-circuit current gain α_{cb} as a function of the emitter bias current. Since stage gain is proportional to the load resistance, it is clear that for cascaded common-emitter stages, the driving-stage gain will vary directly as the input resistance of the driven stage varies. Such variations may come about when one attempts to design a circuit, based on manufacturers' typical data, which may differ materially from that of the transistors at hand. As a consequence of this phenomenon alone, the net gain change per stage may be of the order of 6 db (decibels), which is further compounded in the case of multistage amplifiers. In circuits where the operating point is critical, such variations are intolerable, and yet one does not wish to be faced with the alternative of selecting transistors. Accordingly, a means of reducing such variations is sought in the hope of making transistors with vastly different characteristics look more alike.

The factor of temperature tends to compound the circuit designer's problems. The major effect of a temperature rise is an exponential increase of the collector leakage current I_{co}, causing a corresponding increase of the collector current I_c. This results in a change of the quiescent operating point and, as far as a-c amplifiers are concerned, is equivalent to the effect caused by α_{cb} variations between units.

Self-Feedback as a Means of Gain Stabilization

An effective way of reducing variations is by applying local feedback, aptly called self-feedback. The particular manner in which the feedback is applied to the common-emitter stage is shown in Fig. 4 Current feedback is obtained by the series emitter resistance R_e, and voltage feedback by the collector-base resistance R_f. The current and voltage gains are stabilized by the feedback action, while the terminal impedances are magnified in magnitude but not stabilized. Stability of the magnitude of the terminal impedances results from the base shunting resistance R_b and the collector load resistance R_L, which are, in general, chosen to be an order of magnitude smaller than the value of the terminal impedances in the presence of self-feedback. All of the external resistance elements in the circuit of Fig. 5 contribute toward stabilization of the operating point.

Analysis of the circuit of Fig. 5 yields expressions for the gains and terminal impedances in the presence of self-feedback. The results, given in Table I for the common-emitter amplifier, are extremely useful in predicting transistor performance using typical manufacturer's data. The data of Fig. 6 illustrate some of the virtues of self-feedback. It is seen that, with current feedback alone, the short-circuit input resistance R_{io} is no longer a violent function of emitter current, and, further, that the magnitude is magnified but not stabilized for transistors having different values of α_{cb}. Fig. 6 also shows that R_{io} increases almost linearly with R_e, and in the linear region is given approximately by $\alpha_{cb}R_e$. The last graph of Fig. 6 shows that the voltage gain is almost independent of the value of α_{cb} as R_e is increased. Excellent agreement has been obtained between calculated and measured values of these and other transistor characteristics in the presence of self-feedback.[5] The beneficial effect of self-feedback in reducing the sensitivity of the collector current to changes in I_{co} is shown in Fig. 7, where the operable temperature range is extended considerably over the uncompensated case. It may be shown that for the circuit of Fig. 7 the change in I_c, caused by a change of α_{cb}, is reduced by a factor of 15.[6]

Frequency Characteristics

Those frequency characteristics of the common-emitter amplifier which are pertinent to the stability problem will now be examined.

The quantity of interest is the voltage gain which is given by equation 3 in which K_v is the voltage gain from the base-input terminals (excluding source impedance) to the output.

$$K_v = -\frac{K_i}{Z_i} Z_L \tag{3}$$

where

K_i = current gain
Z_i = input impedance
Z_L = load impedance

If, as is the case for cascaded common-emitter stages, the condition of equation 4 is satisfied, then K_i and Z_i of equation 3 may be replaced by their short-circuit values, namely, α_{cb} and Z_{io} respectively.

$$Z_{o\infty} >> Z_L \tag{4}$$

where

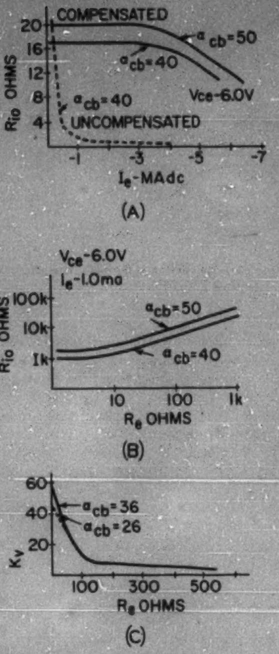
$Z_{o\infty}$ = open-circuit output impedance

Since both current gain and input impedance of a junction transistor are functions of frequency, it is more convenient to consider the frequency characteristics of their ratio, namely, the short-circuit collector-base transconductance defined as:

$$g_b = \frac{\alpha_{cb}}{Z_{io}} \tag{5}$$

Thus under the condition of equation 4 the voltage gain may be expressed by equation 6.

$$K_v = -g_{cb}Z_L \tag{6}$$



(A)

(B)

(C)

Fig. 6. A—R_{io} versus emitter current I_e

SHORT-CIRCUIT CURRENT GAIN α_{cb}

Charge carriers (holes for p-n-p transistors) injected into the emitter reach the collector by a process of diffusion through the base region, and so require a small but finite time to reach the collector. Hence a delay should be expected, but, as the frequency is increased, all the charge carriers do not arrive at the collector simultaneously, with the result that, if the time of arrival amounts to an appreciable portion of a cycle, some of the carriers tend to cancel the effect of others, and the collector current begins to fall off with increasing frequency.[7] Hence, to a first approximation, one should expect the current transfer function to be of the form given in equation 7.[8]

$$\alpha_{cb}(j\omega) = \alpha_{cbo}\frac{e^{-j\omega T}}{1+j\Omega} \tag{7}$$

where

α_{cbo} = low-frequency value of α_{cb}
T = delay time
$\Omega = \omega/\omega_{cb}$

This intuitive approximation is verified experimentally as shown in Fig. 8. Note that for frequencies greater than the cutoff frequency (ω_{cb}), the phase shift increases linearly, thereby manifesting the effects of the delay term. The attenuation of approximately-6db/oct (decibels per octave) justifies the assumption of a single lag factor.

SHORT-CIRCUIT INPUT IMPEDANCE Z_{io}

The frequency characteristic of the input impedance is important in so far as it affects the frequency response of the voltage gain. The loading effects of a frequency variant input impedance on a preceding stage may be neglected when self-feedback and a base shunting resistance are employed. If the frequency dependence of the input impedance is assumed to be caused by an emitter-base diffusion capacitance,[9] then it can be shown that the input impedance exhibits low-pass filter characteristics as given by equation 8 and shown in Fig. 9.

$$Z_{io}(j\omega) = R_{io}\frac{1+j\frac{1}{\eta}\Omega}{1+j\Omega} \tag{8}$$

where

R_{io} = low-frequency value of the input impedance
η = frequency- or ultimate-attenuation ratio $= R_{io}/(r_b+r_e)$ for the common emitter stage

Excellent agreement is obtained between calculated and measured values of the frequency characteristics of the input impedance.

SHORT-CIRCUIT TRANSCONDUCTANCE g_{cb}

From equation 5 and a knowledge of the frequency characteristics of α_{cb} and Z_{io}, g_{cb} may be expressed as

$$g_{cb}(j\omega) = g_{cbo}\frac{e^{-j\omega T}}{1+j\frac{1}{\eta}\Omega} \tag{9}$$

where

g_{cbo} = low-frequency value of g_{cb}
